Mention has been made on a previous occasion of the high bacterial content of this sludge, which varies from 10 to 30 million organisms (G.P.B.) per c.c. A special study has been made of the great variety of protozoa present in the sludge, but up to the present without revealing their rôle in the purification process. A study of the fauna of the sludge does, however, afford valuable information with respect to its presumptive activity.

The following is a typical analysis of the dried sludge: Loss on ignition, 75.2%; mineral matter, 24.8%; total nitrogen as N, 6.4%; phosphate (P_2O_5), 3.8%.

With the view of testing its value as a fertiliser certain field trials have been carried out under the advice of Dr. E. J. Russell, F.R.S., Director of the Rothamsted Experimental Station. A plot of land at the Withington Works, upwards of an acre in area, was divided into 45 plots, the area of each of which was 108 sq. yds. Three crops, viz., spring wheat, mangolds, and cabbage were grown in triplicate, so that each crop was cultivated on 15 plots divided as follows: Three control plots without manure; three plots treated with sulphate of ammonia equivalent to 40 lb. of nitrogen per acre; three plots similarly with sulphate of ammonia equivalent to 80 lb. of nitrogen per acre; while the remaining six plots were manured with activated sludge such that the nitrogen added was equal to that contained in the sulphate of ammonia.

The results obtained with the spring wheat crop are recorded in the accompanying table.

It will be seen that on the average the addition of the sludge has doubled the weight of grain produced, and further that the fertiliser value is equal to that of the nitrogen in the form of sulphate of ammonia, or, in other words, the nitrogen in the sludge is readily available for plant nutrition. This

Crop—Spring Wheat.

Treatment	Corn.					Straw	
	Plots					Total cwt.	Per acre cwt.
	No. 1 lb.	No. 2 lb.	No. 3 lb.	Total lb.	Bushels per acre		
Control unmanured ..	17	16	13	46	11.5	2½	34
Ammonium sulphate 40 lb. N per acre	35	24	37	96	24.0	2½	41
Activated sludge 40 lb. N per acre ..	36	31	22	89	22.2	2½	38
Ammonium sulphate 80 lb. N per acre	35	35	26	96	24.0	3	45
Activated sludge 80 lb. N per acre ..	37	37	34	108	27.0	2½	41

is in accordance with the results obtained by other investigators.

Unfortunately, both the other crops proved failures, the mangolds mainly by reason of too late sowing, and the cabbage as the result of prolonged drought immediately after planting and of the appearance of the cabbage maggot.

While no legitimate conclusions may be drawn with respect to these crops, it may be said that the plots manured with activated sludge showed 100% increase over the control in the case of the mangolds, and from the manured cabbage plots about three times the weight of marketable (shop) plants were obtained as compared with the control plots.

A general idea of the character of the land used for these trials may be obtained from the following results of examination of the soil, carried out by Mr. Ernest G. Gaul, M.Sc., of the Frankland Laboratory, Manchester University, to whom the author is indebted for valuable assistance in connection with this work.

The soil was "air-dried" in the boiler-house. Samples were taken (1) from the S.W. end of the field, (2) from the N.E. end of the field.

In conclusion, it may be stated without hesitation that the two years' experience gained with this installation has demonstrated that the activated sludge process is a practicable process as applied to the purification of the sewage received at the Withington Works.

It is also satisfactory to record that fears with respect to the impracticable amount of scientific control required for the successful operation of the process, with regard to the uniform distribution of air, and in connection with the use of diffusers

have all been found to be without foundation. As a matter of fact, one of the outstanding features of the experience gained with this plant is the lack of trouble with diffusers. As stated previously, the plant has now been in operation for two years, and it has not been necessary to renew any of the 300 diffusers employed. Only eight have been removed from the tank (by undoing the union joint), and these have been replaced in good condition after brushing and blowing. The air pressure (3.1 lb.) is not increasing, so that there are no indications that the diffusers are becoming clogged. On the other hand, further information is required, particularly with respect to the conditions controlling the character and activity of the sludge with specific reference to the role of the higher organisms. This question is at present receiving attention on account of certain occasional difficulties that have arisen, due to the sudden and abnormal "bulking" of the sludge in circulation.

The important problem of dewatering the resultant sludge preparatory to drying has been studied with special reference to the use of centrifugal force both with and without preliminary treatment of the sludge. Comparative trials with filter pressing are about to be undertaken, and it is hoped that it will be possible to publish in due course the results of the research, for which the writer is only partly responsible.

The author has to thank Mr. H. Edwards, manager of the Withington Works, for the capable control of the operation of the plant described, and Mr. P. Gaunt, research chemist, for valuable assistance with respect to the investigations carried out during the past nine months. He is also indebted to the Rivers Committee of the Manchester Corporation for permission to publish the results obtained.

DISCUSSION.

MR. W. THOMSON asked whether a method of separating the solid matter had been tried similar to that adopted in the case of peat, *i.e.*, grinding, the use of high pressure steam, or the electrolytic method. He had noticed that in the elbows of the River Irwell where sewage was precipitated it was filled with a mass of red worms. Had these any purifying effect on the sewage?

MR. J. DRUMMOND PATON mentioned that during an investigation of the humidification of cotton a grey slime had been produced as a result of the water used, and a brown spot formed which came out as a distinct streak on the cloth. The slime when kept at 76° developed brown bodies about $\frac{1}{4}$ in. long. Did these bacilli, whether of fungoid or animal growth, absorb oxygen from the air, which was evidently necessary to produce this coloration, and retain in their own structure an excess of nitrogen, and was there an excess of nitrogen in activated sludge by reason of this same process?

MR. SPEIGHT mentioned that in the author's earlier experiments it had been found that although a satisfactory effluent could be obtained with aeration, yet in order to maintain the activity of the sludge the process had to be carried through to complete nitrification. Frost also produced an inhibitory effect. Had the plant itself been sufficient to maintain the necessary activity?

MR. H. N. MORRIS was of opinion that the success of the activated sludge process depended very largely upon the adoption of an economical method of dehydrating the sludge sufficiently to employ it as a fertiliser. What result could be obtained by the use of a centrifugal?

MISS ROSA ROBINSON asked over what period of time the experiments on the use of fertilisers had been carried out, as she had been informed that some years ago sludge had been tried as a fertiliser near London, and though for a time it proved a

successful fertiliser, yet ultimately it had tended to clog the soil, turning it into a clay-like mass.

DR. ARDERN, in reply, said that the sludge used for the field trials was simply dried on a hot plate, so that the product contained about 15% moisture. The nitrogen content was about 5%, and consequently about four times the weight of sludge was applied as compared with the actual amount of ammonium sulphate used. Mr. Ross had raised a very important point, *viz.*, the relative importance of the time of reaction as compared with the volume of air employed, a question which he was not fully prepared to answer. While it was advantageous to the process to have as long a contact with the sludge as possible, this involved the building of a plant of large capacity. At the designed rate of 250,000 gallons per day there was an average period of retention in the aeration chamber of about four hours. By doubling the rate of flow the average rate of retention was roughly halved, and if practically the same air supply were maintained there was a corresponding reduction in the air consumption. He was not prepared to express an opinion as to the economic limit between volume of air supplied and period of aeration allowed for. He thought the most desirable course was to aim at the lowest possible capacity consistent with the maintenance of satisfactory effluents, for the reason that the more air that could be supplied to the diffusers the less likelihood of trouble ensuing; and, of course, the less tank capacity used the lower capital and sinking fund charges there were on the plant. The main purification change was effected very rapidly, the colloidal matter being removed almost immediately by surface action on exposing the sewage to an intimate contact with the sludge, and the main function of aeration appeared to be to maintain the sludge in a state of reasonable activity, the actual absorption of air being very small indeed. The admission of air into the sewage stream had the effect of creating circulatory action, and thus exposing to the atmosphere a varying surface of the mixture of sludge and sewage. The process was being carried out very successfully by purely mechanical means, without the use of compressed air. While it was true that the volume of sewage dealt with at the Withington works was small as compared with the total flow for the city of Manchester, which was something like 55 million gallons per day, the capacity of the plant under observation was as large a unit as would be provided for a works dealing with the flow received at the Withington works, and was consequently a working scale plant. In connection with the dewatering of the sludge, a continuously operated centrifuge had been used for some months, though the results had not as yet been particularly encouraging, the water content being only reduced to 85%. The effect of electrification had been tried, and it was proposed to continue the experiments, especially in connection with the use of sludge presses. The presence of worms of any type in the activated sludge was accidental and not normal. Dr. Russell had under consideration the question of nitrogen content of the sludge, and was endeavouring to prepare an accurate balance sheet of the nitrogen as between the sewage treated and the effluent leaving the tank. A number of determinations had already been made, but the sewage was such a heterogeneous mixture, and there was so many small errors in sampling, that the results were rendered uncertain. The effect on the cloth, mentioned by Mr. Paton, was probably due to iron organisms which were sometimes found in settlement ponds, though, as a rule, they were not present in the sludge. There was no smell noticeable from the air escaping from the sewage, and very little likelihood of it containing any amines

or allied nitrogenous compounds. The inhibitory effect of frost had been practically negligible, the only result being a rather reduced amount of nitrification. The agricultural trials referred to in the paper had been undertaken during the previous season only. There was, however, no reason to anticipate any deleterious cumulative effect, which could only arise from an undue grease content; activated sludge contained very little greasy matter. The trials referred to by Miss Robinson probably related to the use of ordinary sewage sludge, which had not only a very much lower nitrogen content than activated sludge, but was liable to contain a much higher percentage of grease.

Communications.

THE “HEAT-RISE” METHOD OF TESTING SULPHURIC ACID AND OLEUM.

BY R. CURTIS AND F. D. MILES.

In the manufacture of sulphuric acid and oleum by the contact process it is essential for satisfactory control to be able to determine rapidly and frequently the strengths of the acids in the various reservoirs of a unit. In 1916 the authors were led to consider the various methods available, in order to find one suitable for use on the oleum plants of H.M. factories.

The method of titration with alkali requires care, skill, and time, particularly when used for oleum samples. As the most accurate means of estimating total acidity it is necessarily used for the standardisation of other methods. It has, however, the disadvantage of being less sensitive to small variations in free trioxide content of oleum than a method which estimates this free trioxide directly and is not immediately concerned with the total acid contents. Direct determination of the percentage of free SO_3 is achieved by the method of titration with water (Parker, this J., 1917, 692); but here also more skill is required than can be relied on if the estimations are to be carried out by operatives on the plant.

A method of estimation depending on the rise in temperature consequent on mixing oleum and sulphuric acid of about 93% was worked out by Howard (this J., 1910, 3). Amounts of 100 grms. of each of the acids were mixed in a small silvered vacuum flask. It was found by us that for plant purposes the use of much larger amounts of acid—about 400 grms. of each—was a marked improvement. The mixture cools slowly and the resultant temperature can be read with fair accuracy. Only the simplest apparatus is required—a straight-

sided earthenware mug holding about a pint, two measuring cylinders, and a thermometer. The thermometer should have the scale marked inside the stem and should respond rapidly to changes of temperature. It may conveniently be encased in a thin steel tube filed thin at one end and pierced with a number of holes to allow the acid to have free access to the bulb.

The method of carrying out the test is given below. The standardisation was carried out with samples of oleum and acid the composition of which had been very carefully determined by alkali-titration. The results were plotted as graphs, and from the smooth curves the values given in the table were read off. They have received substantial confirmation from other observers.

In every case the samples should be cooled to 25°C . at least.

(A) *Test for oleum* (of not more than 25%). 200 c.c. of oleum (temperature $a^\circ\text{C}$.) is poured quickly, with vigorous stirring, into 200 c.c. of sulphuric acid at $b^\circ\text{C}$. in the mug. The rise of temperature $= c - \frac{1}{2}(a+b)$, where c is the maximum temperature of the mixture. The percentage of free SO_3 is found from Table I. After mixing the liquid should not fume.

Variation in the strength of the sulphuric acid between the limits of 92.5 and 94.5% was found to have no influence on the result. In five exactly similar experiments the rises of temperature were 23° , 22.8° , 22.5° , 22.5° , 23.2° , showing a maximum variation of 0.4° from the mean (or 0.2 – 0.3% free trioxide). The results are reliable within 0.5% free trioxide, or 0.1% H_2SO_4 .

(b) *Test for sulphuric acid* (96–100%).—The procedure is as above, but the acid is poured into the oleum (20–25%). Rise $= c - \frac{1}{2}(a+b)$, as before. Table II. is used for this case. After mixing the liquid should fume. If it does not fume, test again, as in c. Variation in the strength of the oleum from 18 to 25% was found to be without effect if free SO_3 were in excess at the end of the test. The results are reliable within 0.3% H_2SO_4 .

(c) *Test for sulphuric acid* (88–96%).—100 c.c. of the acid sample (temperature b°) is mixed with 300 c.c. of oleum (20–25%, temperature a°). Rise $= c - (3a+b)/4$. Table III. is used here. After mixing the liquid should fume. As before, small variations in the strength of the oleum have no effect. The error should be less than 0.5% H_2SO_4 .

The procedure described is in practice extremely simple and takes only a few minutes. It was carried out by the men and girls engaged in operating the plant, and was found to yield excellent results at Queen's Ferry, Gretna, Avonmouth, and other of H.M. factories. In one instance it was used to carry out half-hourly tests of each reservoir of an oleum unit for many weeks together. The test may

also be recommended for many other plant operations where the strength of sulphuric acid is required, and it has already been used in connection with sulphuric acid concentration, acid mixing, nitric acid manufacture, and sulphonation.

The data on which the tables are founded were obtained from acid and oleum samples which were almost pure, with the exception that they contained sufficient suspended matter to render them cloudy. In the case of acids containing much impurity some slight deviation may be expected. Thus, at H.M. factory, Pembrey, it was observed that oleum made from sulphuric acid recovered from T.N.T. waste acid always gave a greater rise of temperature than is given in the tables, i.e., the figures for SO_3 content had to be reduced about 1%. With oleum made from sulphuric acid recovered from nitrocellulose or nitroglycerin waste acid no such deviation appears to occur.

A SYNTHESIS OF $\beta\beta$ -DICHLORDIETHYL SULPHIDE (MUSTARD GAS).

BY J. E. MYERS AND H. STEPHEN.

On November 20, 1917, we were invited to undertake research on the synthesis of mustard gas. We were informed at the time of the existing synthesis of Victor Meyer (Berichte, 1886, 19, 3260), and owing to the unsuitability of this method we made the suggestion that the compound might be formed according to the reaction:—

We were informed that this reaction did not give the desired compound, and we were given to understand at a much later period that prior to our work attempts had been made to prepare mustard gas by this method, but these had failed to give more than a 7% yield.

After preliminary experiments and a consideration of the work of Guthrie (Quart. Journ. Chem. Soc., 1860, 12, 116; 1861, 13, 134) and Niemann (Liebig's Annalen, 1860, 113, 288) we decided to test the suggestion which we had made at the outset.

Ethylene was prepared by passing the vapour of ethyl alcohol over pumice saturated with orthophosphoric acid heated to 220°C ., and purified to remove vapours of alcohol and water. The ethylene was passed into sulphur dichloride contained in a wash bottle which was cooled. A vigorous reaction took place, and when no further absorption of ethylene was observed the liquid was of a bright yellow colour. During the reaction a considerable amount of hydrogen chloride was evolved.

The crude product was tested for toxicity by application to the skin. A slight smear on the forearm caused acute blistering from the wrist to the elbow and general swelling of the whole arm.

The liquid was found to give on distillation some 20 to 25% of sulphur monochloride, and independent analysis gave some 65% of mustard gas. This preparation was carried out on December 31, 1917, and was repeated frequently during the following week.

Being satisfied of the great toxicity of the product and of the probability that the method could be conveniently used for the production of mustard gas, information of the method and a sample of the product were sent on January 6 and 8, 1918, to the authority inviting us to help in the work.

A consideration of these early experiments showed: (1) That the sulphur dichloride contained sulphur monochloride, and (2) that there was a secondary reaction in which sulphur dichloride chlorinated the mustard gas. The latter effect was no doubt due to the decomposition $2\text{SCl}_2 = \text{S}_2\text{Cl}_2 + \text{Cl}_2$, which was hastened by the heat of the first reaction.

We also examined the sulphur dichloride, and worked out a method for the preparation of the pure substance. In our later experiments we started from this pure dichloride, diluting it with monochloride as desirable.

We then turned our attention to the problem of avoiding the secondary reaction of chlorination. The question of the action of sulphur monochloride on ethylene was being examined elsewhere.

Our next experiments therefore consisted of allowing the dichloride to drop on to a cooled surface in presence of an excess of ethylene. In this way we were able to prepare the product continuously, and when the cooling surface was at about 8°C . we frequently obtained deposits of crystalline "mustard gas." Although this result indicated a high degree of purity in the product, it had the great disadvantage that the solid was very easily chlorinated by succeeding drops of dichloride. We were able, however, to prepare rapidly and conveniently a product which contained 70% of mustard gas with a melting point varying in different samples from $+1^\circ$ to -6°C . This series of experiments was commenced on January 30, 1918, and was demonstrated a day or two later to representatives of an important works concerned in the matter, who set up a semi-large-scale apparatus which by the end of February produced a material very similar to the laboratory product. This we believe to be the first works preparation of mustard gas in this country.

We still sought to reduce the chlorination of the mustard gas, and it was suggested by Sir Richard Threlfall and Prof. A. Lapworth that the chlorination might be overcome by spraying the dichloride into an atmosphere of ethylene, so that the former might be so quickly combined that it would have no opportunity of spoiling the product. In collaboration with Prof. Lapworth and Mr. F. Royle we tested this method, using an atomiser of the scent-spray type whereby the dichloride was sprayed by means of the ethylene. Our first experiments were carried out in a four-litre flask, but eventually we used a 200-litre vessel.

The reaction proceeded in a very satisfactory manner, as will be seen from the following table of typical results. The reaction was almost instantaneous, and consequently we were able to prepare the substance rapidly and continuously:—

Starting material.	M.pt. of crude product. $^\circ\text{C}$.	% Mustard gas by distillation.	M.pt. of mustard gas fraction. $^\circ\text{C}$.
68% SCl_2	—	70	12
80 " "	—	80	10
68 " "	0	88	9
75 " "	2	93	8
80 " "	4	87	5

The variations in the results are due to modifications in the apparatus used. It was found that the best starting material was a mixture of 75% of dichloride and 25% of monochloride. During the reaction some of the latter is used up.

This method we found to be capable of producing a very suitable toxic material, and the method of working could be readily modified to give a product which had a suitable freezing point and which deposited no sulphur.

During the work we investigated the possibility of quickly removing mustard gas from the exterior of shells, and after experimenting with a number of oxidising agents we found that a solution of sodium hypochlorite containing sodium bicarbonate was most efficient in this respect, the hands or pieces of apparatus being almost instantaneously freed from the toxic substance.

In concluding this very brief summary of our work we wish to thank Sir Richard Threlfall and

Prof. Dixon and Lapworth for the kind help which they gave us in many ways.

SUGAR IN OAT STRAW AND CATTLE FOODS.

BY S. HOARE COLLINS AND ARNOLD SPILLER.

Most practical farmers attribute much virtue to sugar in cattle foods, but few data have been published on the proportion of sugar in many of the commoner foods. Bodmer, however, has recently referred to the sugar in desiccated coconut (*Analyst*, 1920, 45, 18). The matter is of practical importance, if only because good results may be erroneously ascribed solely to a high priced condimentary food rich in sugar, when the cattle are being fed also with common foods equally rich in sugar. Kellner appears to have ignored the value of the sugar in fodder and meals. The superiority of early cut over late cut oat straw is probably due to the greater content of sugar, which renders the early cut more palatable and nutritious. The fermentation of moistened straw converts the sugar into alcohol, lactic acid, and butyric acid, all of the hope that others will be induced to make further if much advantage is gained thereby.

The following preliminary results are given in the hope that others will be induced to make further investigations:—

Description of foodstuff.	Total sugar. %	Invert sugar. %
Earth nut cake, new, now in use at Cockle Park	8.46	nil.
Palm kernel cake, new, now in use at Cockle Park	3.05	trace.
Oat straw, cut before quite ripe (north country practice)	5.61	not determined.
Oat straw, yellow part hand-picked from same sample	6.32	5.19
Oat straw, green part hand-picked from same sample	6.47	5.5
Oat straw, cut green 18 months ago; sugar perhaps diminished by fermentation	2.89	Not determined.
Oat straw, cut fully ripe 18 months ago; sugar perhaps diminished by fermentation.	1.5	Not determined.
Oat straw, from Midlands, cut fully ripe in 1918, sugar perhaps diminished by keeping	Nil	
Oat straw, from Midlands, 1919 crop, cut greenish	5.00	4.18
Castor cake*, old laboratory sample	4.63	Not determined.

* Poisonous unless seed has been deprived of its ricinin.

From the above results it will be seen (1) that there is ample evidence that when cut green, oat straw may contain upwards of 6% of sugar, mostly invert; (2) that when cut fully ripe the sugar is mostly lost.

The amounts of sugar were determined by Fehling's volumetric method. Some difficulty was found in obtaining clear solutions. The cuprous oxide, instead of separating in bright red clots, leaving a clear liquid on standing, formed a yellow muddy liquor, with the reduced copper persistently remaining in suspension. In many cases the colloidal nature of the solution, after clearing with lead acetate, was due to the presence of fatty substances or essential oils, which we find can be removed by a previous extraction with ether. The use of animal charcoal was found to be of little value.

To determine the sugar, we prepare an aqueous solution, using 5 grms. of food, extract with ether, add 5 grms. of lead acetate and 250 c.c. of water. This mixture is allowed to stand overnight. After filtration 50 c.c. of the solution is acidified with 5 c.c. strong hydrochloric acid and warmed gently

so that it reaches 60° C. after twenty minutes. Any lead chloride is filtered off, anhydrous sodium carbonate added in excess, and the filtered liquid titrated with Fehling's solution.

The invert sugar content of the food is determined in the same way, omitting the heating with hydrochloric acid.

THE CHANGE OF REFRACTIVE INDICES OF FIXED OILS WITH TEMPERATURE.

BY A. F. JOSEPH, D.SC., F.I.C.

In a paper on the above subject (this J., 1919, 392 T), by C. Harold Wright, a means of calculating the refractive index of a fixed oil at a particular temperature from the known result for another temperature is suggested. His formula—

$$n = (n_1 - 1)(1 - 0.0076t_1)/(1 - 0.0076t) + 1$$

(where n and n_1 are the refractive indices at temperatures t and t_1 respectively)—is developed from Gladstone and Dale's expression for the refractivity constant $(n-1)/d$ (independent of temperature), Mendeleef's observation that most liquids expand according to the linear law $V = V_0(1 + kt)$, and his own observations that the coefficient of thermal expansion is the same for all fixed oils.

In a footnote he points out that the much simpler expression $(n - n_1)/(t_1 - t)$ (i.e., the change of refractive index per degree, or dn/dt) is not a constant; in fact, however, it compared quite favourably with his own for constancy. Thus, for the 20 oils quoted from Procter's work, the simple constants dn/dt are as follows:—347, 369, 340, 365, 351, 362, 356, 389, 349, 367, 362, 376, 364, 371, 356, 369, 376, 356, 380, and 371, all $\times 10^{-6}$. The mean value of the above figures is 0.000363 and the average deviation from the mean 0.000010, or 2.8%. The mean value for Wright's coefficients is 0.000751 and the average deviation from the mean 0.000023, or 3.1%.

The more conventional "coefficients of variation" $\frac{100}{M} \sqrt{\frac{\sum (x^2)}{n}}$

where M is the arithmetic mean of n results and x the difference of each from it, are 3.4 and 3.3 respectively.

It was, indeed, hardly necessary to put forward a new method of applying a temperature correction to refractive indices for practical purposes, as Tolman and Munson (*J. Amer. Chem. Soc.*, 1902, 754) had already demonstrated what is illustrated by the above figures, i.e., that dn/dt for different oils is very nearly a constant, the value of which they placed at 0.000365.

It appears to the present writer that Wright's method of correction does not introduce either increased simplicity or accuracy in practical work; it is, moreover, actually based on a hardly justifiable assumption. His formula, as stated above, assumes that the coefficients of thermal expansion of oils, and of fats and waxes, are approximately the same. But from a study of the figures given in a previous paper (this J., 1907, 514) it appears that these are in no closer agreement than the values dn/dt . Thus, for twenty of the substances dealt with in the above paper (neglecting those such as stearic acid and paraffin wax, which are not true oils and fats, and which give abnormal results) the mean value for the coefficient of thermal expansion is 0.000699 and the average deviation from it is 0.0000233, or 3.3%.

It is therefore suggested that correction of refractive index for temperature should be made by the simple method of adding or subtracting 0.00036 for every degree of temperature correction. Thus, in the example given by Wright, the refractive index of rape oil at 28.8° being 1.4696, the correction for 40° is $11.2 \times 0.00036 = 0.0040$, giving 1.4656 for the desired figure, as against 1.4655 using Wright's factor.

MR. QUINTIN MOORE IN THE CHAIR.

WETTING POWER AND ITS RELATION TO INDUSTRY.

BY W. H. NUTTALL, F.I.C.

When a drop of liquid is placed on a level solid surface there are three possibilities; either the drop will retain its globular form, as, for example, mercury on glass, in which case there is little or no wetting of the solid by the liquid; or the liquid will distribute itself evenly over the surface to form a continuous film, as, for example, benzene on glass, which is an instance of complete wetting; or, lastly, the drop of liquid will flow to some extent and form a definite angle of contact between the surface of the solid and the air surface of the drop. Such a condition is to be regarded as partial wetting, and is exemplified by the behaviour of a drop of water on a slightly dirty glass or metal surface. The smaller the angle of contact which a liquid forms with a solid surface, the higher is its wetting power, and with complete wetting, the angle of contact becomes zero.

The ability of a liquid to wet a solid is a property which is made use of in many technical processes of great diversity. A method of comparing the wetting power of different liquids is a frequent necessity in such processes, yet the methods adopted show that the principles upon which wetting depends are not generally understood. Whilst the process of wetting is possibly a highly complex one and not yet completely understood, yet there are certain fairly well defined factors upon which wetting mainly depends, attention to which is usually sufficient to overcome most of the difficulties encountered in technical processes in which wetting in its broadest sense plays a part.

Quincke,* in 1877, was the first to point out the more obvious of these factors, and I will briefly reiterate them.

The spherical form assumed by a drop of falling rain is the result of the pressure exerted by the surface film, usually known as surface tension. A drop of oil suspended in dilute alcohol of the same density likewise assumes a spherical form as a result of the tensions exerted at the interface of the oil and dilute alcohol. This tension is usually known as interfacial tension, and will exist at the interface of any two immiscible liquids. Now consider the surface of a solid. The conception of a stretched film exerting a distinct tension at the surface of a solid is not so easy. Yet such undoubtedly exists, although its presence cannot be readily demonstrated. Further, in the case of a liquid in contact with a solid, judging from analogy, we should expect an interfacial tension to exist between the liquid and the solid.

Let us imagine that a drop of liquid has been placed upon the surface of a solid. Its behaviour will be mainly determined by the relative values of three distinct tensions. (If the drop is sufficiently small, the effect of gravity need not be considered.)

There is the surface tension of the liquid (T_1); the surface tension of the solid (T_2); and the interfacial tension of the liquid to the solid ($T_{1,2}$). The surface tension of the liquid (T_1) will be

exerted in the direction of the arrows at A (fig. 1), and will tend to maintain the drop in its spherical form. Similarly, the interfacial tension ($T_{1,2}$) will be exerted in the direction of the arrows at B, and this tension will also tend to roll up the drop

FIG. 1.

and maintain its spherical form. The surface tension (T_1), however, will have the opposite effect; it will be exerted in the direction of the arrows at C, and will strive to draw out the drop into a more and more lenticular form; the angle of contact of the drop will tend to become smaller and smaller until finally the latter forms a continuous film over the surface of the solid. For this to happen it is not difficult to see that the surface tension of the solid T_2 must exceed the sum of the surface tension of the liquid T_1 and of the interfacial tension $T_{1,2}$ —

$$i.e., T_2 > T_1 + T_{1,2}$$

Since two of these tensions, viz., the surface tension of the solid T_2 and the interfacial tension between the solid and the liquid $T_{1,2}$ are indeterminate, direct experimental verification of this inequality is not possible. Röntgen*, however, has succeeded by indirect means in establishing its validity for the system rubber/water. Certain indirect determinations which I have made are also in agreement with the inequality.

By a method to which I shall refer later, it is a comparatively simple matter to determine the interfacial tension of a thick oil to a soap solution. Both the surface tension of the oil and of the soap solution can be found by any of the usual methods. If a microscope slide is smeared lightly and evenly with the thick oil, the surface of the oil approximates sufficiently closely for the purpose of the experiment to a solid surface, the surface tension T_2 of which, as well as its interfacial tension to soap solution $T_{1,2}$, are known. In my experiments I used castor oil and two soap solutions of different strengths. The results obtained are tabulated below, the figures being given in dynes per cm.:—

Soap solution.	Surface tension of soap solution. T_1 .	Surface tension of oil. T_2 .	Interfacial tension of oil and soap solution. $T_{1,2}$.	($T_2 - T_1 - T_{1,2}$) Wetting power.
A.	34.6	38.1	0.4	+ 3.1
B.	40.8	38.1	10.4	-13.1

If the relation between the three tensions, stated above, is valid, since in the case of solution A the expression $T_2 - (T_1 + T_{1,2})$ is positive, we should expect that this solution would wet and form an even film over a slide prepared with castor oil; also, since with solution B the same expression is negative, we should not expect wetting. This was actually found to be the case. The greased slide was completely covered and wetted when solution A was poured over it; whilst a similarly prepared slide, on being treated in the same manner with solution B, was found to assert its greasy nature.

* "Mittheilung Einzelner Versuche aus dem Gebiet der Capillarität," Wied. Annalen, 1878, II., 321-28.

the soap solution running into drops and failing to wet.

From the above inequality it is evident that for a liquid to possess a high wetting power it must have a low surface tension (T_1) and also a low interfacial tension ($T_{1,2}$). Further, it is evident from fig. 1 that the effect of reducing the interfacial tension ($T_{1,2}$) will be to cause the liquid to spread over the surface of the solid, even if the surface tension T_1 is fairly high or, in other words, it is the interfacial tension $T_{1,2}$ rather than the surface tension of the liquid T_1 , which is the main determining factor in wetting. The figures in the above table lend support to this conclusion. In fact, in complete wetting, the interfacial tension $T_{1,2}$ is reduced practically to zero.

The process of wetting, however, is not so simple as would appear from a consideration of the above inequality or of its experimental verification which, after all, is purely of theoretical interest. In practice account must be taken of at least two other factors, which, under certain conditions, may cause the above relationship to fail entirely.

The first of these disturbing factors is concerned with the solvent properties of the wetting liquid. It usually happens in actual practice that the surface to be wetted is already coated with a waxy or greasy film. If the surface of the solid is to be reached, the wetting liquid must have a certain solvent action on this wax or grease. If the interfacial tension of the liquid is low, this solvent action need not be great, as, if the surface of the solid is reached in any one place, the waxy or greasy layer will be displaced by the wetting liquid, because its interfacial tension to the solid will be lower than that of the wax or grease to the solid. The detergent property of soap is due to this action. If, on the other hand, the wetting liquid has no solvent action on the wax or grease there is no actual contact between the liquid and the solid, and therefore no wetting. Thus, for example, it is probable that the reason why mercury fails to wet the surface of so many solids is not entirely due to its high surface tension, but also to the fact that it is incapable of dissolving the surface layer of moisture which adheres to most solids.

The second factor, liable to vitiate conclusions drawn from the expression conditioning wetting, is concerned with the phenomenon known as surface concentration or capillary adsorption. If, with increasing concentration, the surface tension of an aqueous solution of a substance decreases it will be found that the solute tends to aggregate in the surface layers of the solution.* Saponin, proteins, and various other substances possess this property to a marked degree. Aqueous solutions of dyes, kept in stoppered bottles so as to preclude evaporation, frequently show a visible accumulation of the dye at the surface. Lewis† has calculated that with a 0.25% solution of sodium glycocholate there is an extremely thin surface layer, the degree of concentration of which is about 160 times that of the bulk. The result of this surface concentration is the peculiar superficial viscosity or rigidity, first observed by Plateau‡. In the case of saponin this surface viscosity or rigidity may be easily demonstrated. If a bubble is blown with a 1% solution of saponin, the bubble film will be found to be imperfectly elastic and quite different from a soap film. If air is withdrawn whilst the orifice of the pipe is held in a vertical plane, so as to disturb the symmetry of the bubble, the shrinking film assumes a crinkled appearance, until finally there

results a vertical semi-solid cylinder with almost opaque walls.

Vermorel and Dantony* were the first to point out that a liquid exhibiting surface viscosity to a marked degree had in consequence a high wetting power. Solutions of saponin have marked wetting powers, although the surface tension of such solutions is comparatively high. Thus a 1% solution of saponin is capable of wetting a glass plate coated with paraffin wax, although a 5% solution of soap fails to do so. The wetting power of solutions of saponin, gelatin, etc., seems to depend largely upon their capacity to form liquid planes, the high superficial viscosity of which prevents rupture and running together to form drops.

The phenomenon of surface concentration is, however, of interest from another point of view. It has long been observed that the apparent surface tensions (static) of soap solutions are practically identical for all concentrations between 10% and 0.1%.† More recent investigations have, however, shown that this statement is only true if the surface tension determination has been carried out on an old surface. Rayleigh‡ succeeded in showing that, if the surface tension of a 0.25% solution of sodium oleate is measured within 1/400 of a second after the formation of the surface, the surface tension (dynamic) approximates closely to that of water. This initial tension, however, quickly falls until the ordinary value for the surface tension is reached. Rayleigh's results have been repeatedly confirmed by other workers, and a distinction is now drawn between what are known as the *static* and *dynamic* surface tensions. The static surface tension is the one obtained, when the determination is carried out on an old surface, as with the capillary rise and stalagmometer methods. The term "surface tension" as generally used in text-books refers to static surface tension. The dynamic surface tension, on the other hand, is the value obtained with determinations on perfectly fresh surfaces, as in the methods involving the use of jets, surface ripples, etc. The dynamic surface tension is always ill-defined, its value is dependent upon the age of the surface, and gradually passes to that of the static tension.

This strange behaviour of soap and other solutions is to be traced to the phenomenon of surface concentration or adsorption. Soap is a substance which is positively adsorbed, that is, it accumulates in the surface layers of a solution, and as surface tension is a function of the surface layers only, the presence of this concentrated surface pellicle of soap solution will be evidenced by a low surface tension. The peculiar behaviour of a soap solution referred to above would therefore find a ready explanation in the production of this surface pellicle of soap, the concentration of which is but little affected by that of the bulk of the solution. The formation of this surface pellicle is not instantaneous, but requires a certain lapse of time; hence the existence of the dynamic and static surface tensions and their gradual passage one into the other.

Having reached this stage we are now in a position to consider some of the more common methods which have been used in comparing the wetting power of different solutions. The method most frequently adopted is a determination of the surface tension of the solution. Can the surface tension of a solution afford a reliable indication of its wetting power? I think not, and for two reasons. Firstly, we have seen that the conditions for a

liquid to wet a solid surface are expressed in the inequality

$$T_2 > T_1 + T_{1,2}$$

From what has already been said, it is clear that of those three tensions it is the interfacial tension which is the predominating factor in determining wetting. Obviously some regard must be given to the nature of the surface to be wetted, and of the three tensions concerned, the surface tension of the liquid is the only one which has no connection with the surface of the solid. It is thus certainly the least desirable of the three upon which to base a judgment of wetting power. The frequently recurring statement that liquids with a low surface tension wet more readily than those with a higher one is not strictly true, for it does sometimes happen that a liquid with a high surface tension and low interfacial tension wets better than one with a low surface tension and a high interfacial tension.

Secondly, the surface tension of a soap solution cannot be accepted as a criterion of wetting power, because, as we have seen, the determination of the surface tension (static) is seriously vitiated by surface concentration effects. Solutions containing respectively 10%, 1%, and 0.1% of oleic soap all possess much the same surface tension (static), but their wetting power towards, say the leaf of a tree, is quite distinct.

Reference to the above table, in which figures are given for the wetting power of various dilutions of sodium oleate, will show that up to 2% of fatty acid there is a progressive increase of wetting power with the concentration. Further, whilst, except in the case of extreme dilution, there is but little difference in the values of the surface tension, the values for the interfacial tension go more or less hand in hand with those of the wetting power. If, therefore, it is convenient to estimate only one of the three tensions concerned in wetting, the interfacial tension is certainly preferable to the surface tension.

Another method of comparing the wetting power of solutions has been based upon a comparison of the amount of liquid which adheres to a solid object of standard size and shape, which is dipped into the liquid and then carefully withdrawn. But we have seen that the power to wet is dependent upon one or both of two main factors: (1) a low interfacial tension and (2) a high surface viscosity. One of the results of a low interfacial tension, where surface concentration effects are not particularly marked, is to cause the liquid to "run" easily. In the test under consideration the low interfacial tension of the liquid would cause it to wet the immersed solid, from which, on withdrawal from the fluid, all excess of liquid would "run" off very

rapidly leaving behind, however, a continuous film. The effect of a high surface viscosity would be in the opposite direction; as soon as a thin film of liquid was produced surface concentration would come into play, as a result of which draining would be largely hindered. The amount of liquid adhering to the solid would be the resultant of two opposite effects, and as such we should not expect it to differ in any marked degree, whatever the solution under investigation—a view which experiment confirms.

It is a matter of common experience that an emulsion of oil in any liquid always possesses good wetting properties, and one method of measuring wetting power is by a comparison of the emulsifying power of the liquids in question towards a standard oil. Theoretically the method is sound, and it may be of interest to point out why.

Donnan* has shown that a soap solution acts as an emulsifier by virtue of its low interfacial tension with respect to oil. The result of this low interfacial tension is two-fold. Firstly, the soap becomes concentrated at the surface of the oil globules, and owing to the surface viscosity produced thereby the film of liquid intervening between two oil globules resists thinning and the consequent coalescence of the globules. This explanation also probably holds for emulsifying agents other than soap. Certainly in milk, which is a good representative emulsion, the globules of fat are surrounded by a tenacious coating, which undoubtedly consists of adsorbed albuminous matter from the serum. It is so tenacious that it can partially protect the fat globules from the solvent action of ether, as it is impossible to extract the fat completely from milk by ether without drying the milk and so destroying the adsorbed film surrounding the globules. In fact, if the oil content in an emulsion is large, the surface rigidity or viscosity at the interface of each of the oil globules becomes visible in the thickening which results in the emulsion. The viscosity of a concentrated oil emulsion is considerably higher than that of the oil and of the emulsifying solution, and this increase in viscosity may be regarded as the result of the surface viscosity effects occurring at the interface of each oil globule and the aqueous matrix.

Something of the character of this adsorbed film which is formed at the surface of the oil globules may be gathered from the following simple experiment. If a fair-sized globule of thick mineral oil is placed on the surface of a somewhat concentrated solution of saponin, and by means of pipette saponin solution is introduced into the centre of the floating globule of oil, it is possible to produce a bubble of oil filled with saponin solution, the bubble itself floating within the external solution. The thin layer of oil forming the skin of the bubble, whilst of itself quite incapable of giving a tenacious film, has under the conditions of the experiment become so fortified, both internally and externally, by the saponin adsorbed on each interface that a comparatively rigid structure results. This bubble of oil is in fact a large scale representation of the condition of a minute globule of oil in an oil emulsion, except, of course, in the latter case, the globule of oil contains none of the emulsifying agent within itself.

The second reason why a liquid, possessing a low interfacial tension with respect to oil, should possess high emulsifying powers is a simple one. The force tending to break the aqueous film intervening between the globules of oil is that of the interfacial tension of the aqueous liquid to the oil, and if this is small, it is not sufficiently strong to withdraw the aqueous film separating the globules. Thus, the main requisite for a liquid to have a high

* "Ueber die Natur der Seifenemulsionen," Z. physikal. Chem., 1893, 31, 42-49.

emulsifying power to an oil is that it shall possess a low interfacial tension towards that oil. We have already seen that the main factor in determining the wetting power is a low interfacial tension towards the surface to be wetted, and, as in actual practice such surfaces are usually of a greasy character, it follows that a good emulsifier is also a good wetter, and that, therefore, emulsifying power is a very good indication of wetting power.

One other power of most wetting liquids has been suggested as of use in the comparison of wetting power; that is, foaming power. The property of foaming and the factors which lead to the formation of a permanent foam have formed the subject of a considerable amount of investigation by various workers, amongst whom may be mentioned: Plateau,* Quincke,† Rayleigh,‡ Donnan,§ Shorter,¶

A foam is now generally regarded as an emulsion of air in a liquid. Support is lent to this view by the fact that the requisite conditions for the production of a permanent foam are exactly analogous to those necessary for the formation of a permanent emulsion of oil in an aqueous liquid. These we have seen to consist in (1) a high surface viscosity of the intervening film, and (2) an interfacial tension so low as to be incapable of breaking this film. In the case of an oil emulsion the intervening matrix prevents the coalescence of the oil globules, and similarly, in the case of foam, it is the intervening matrix which prevents the coalescence of the air bubbles. With emulsions of oil, therefore, it is the interfacial tension of the aqueous liquid to the oil which is the determining factor; with foams, on the other hand, it is the interfacial tension of the aqueous liquid to air, i.e., the surface tension of the aqueous liquid, which is of importance. The property of giving a lasting foam, therefore, indicates that the liquid possesses (1) the property of surface concentration, such as saponin solution, which shows exceptional frothing power, and (2) a low surface tension, such as soap solutions. Since, however, wetting power is mainly dependent on a low interfacial tension, the ability to give a permanent foam does not necessarily indicate a high wetting power. As a matter of fact, I have examined liquids which, whilst possessing an extremely low interfacial tension towards oil and thus a high wetting power, were quite incapable of giving a foam.

It will now be recognised that whether we are concerned with the comparison of emulsifying power or of wetting power, it is the interfacial tension which is the deciding factor, and that a simple method of determining the interfacial tension would afford us a quantitative test of considerable practical value. Unfortunately, as I have already pointed out, there is no simple and direct method by which the interfacial tension of a liquid to a solid may be measured, but in the case of two liquids, as an oil and a solution of soap, the determination of their interfacial tension offers no difficulty. And since in the majority of cases the surface which we are concerned in wetting is a greasy or waxy one, there seems to be no valid reason why, for the purpose of comparison of wetting power, a thick oil should not be taken to represent the solid surface. This is a method which I have followed for some years with highly satisfactory results.

The determination of the interfacial tension between an oil and a solution of soap is carried out

by means of Donnan's "drop pipette" (*loc. cit.*). The pipette is filled up to a mark on the upper limb with a selected standard oil, lowered into a glass jar containing a given volume of the aqueous liquid under examination, and clamped in an upright position. The upper stopcock is then opened, and the number of drops of oil counted until the level of the oil in the pipette sinks to a mark on the lower limb. The size of the drop and hence the drop number is dependent upon (1) the interfacial tension, (2) the size of the aperture of the pipette, (3) the difference in density between the oil and the aqueous liquid, and (4) a constant depending upon the size of the aperture, the difference in density, and the interfacial tension. If absolute values are required, all these four factors must be taken into account. The calculations are somewhat tedious, but have been described fully by Lewis (*loc. cit.*).

Where comparative values only are required, as in the determination of wetting and emulsifying powers, the interfacial tension may be taken as inversely proportional to the number of drops since the diameter of the aperture remains constant, whilst the difference in density between the oil and the fluid examined does not usually vary greatly. Since the wetting or emulsifying power varies inversely as the interfacial tension, the wetting or emulsifying power is directly proportional to the drop number (compare table p. 69 r.). I have described this method more fully elsewhere in collaboration with Cooper.* We realise that the method is open to certain objections, but we have found by experience that it affords a ready means of determining and expressing in numerical value the wetting and emulsifying power of a solution. The apparatus required for the test is simple, and if attention is given to a few simple precautions reliable results are easily obtained. The method, unfortunately, has its limitations. When employed with solutions of gelatin, saponin, etc. these should be extremely dilute; with stronger solutions of such substances surface concentration at the interface of the oil and aqueous solution becomes so marked that quasi-solid surfaces are produced, with the result that the drop number and hence the value found for the interfacial tension are completely vitiated.

In conclusion, a few of the many industries in which wetting power plays a more or less important part may be mentioned very briefly.

Perhaps the most obvious is the flotation process for the separation of minerals, an industry which has made enormous strides during recent years, enabling, as it does, low-grade tailings, hitherto wasted, now to be extracted profitably. The principle upon which the process is based is the fact that the same liquid wets a mineral sulphide and quartz to a different extent, and further, that this difference in "wettability" is accentuated by the addition of a small quantity of a suitable oil, which, by being selectively adsorbed on to the surface of the sulphide, renders it more difficult to wet. Similarly, by the addition of an acid or alkali, the surface of quartz is rendered more easily wettable. At the recent Scientific and Industrial Exhibition held in Glasgow a process was shown working in which fine particles of coal were separated from earthy matter through their difference in "wettability" by a common solution.

There are numerous other industries in which wetting power and emulsifying power play an important, though perhaps not such an obvious, part. Take the case of coal-tar disinfectants. Why should an emulsified disinfectant possess a higher disinfecting coefficient, as measured by the Rideal-Walker or similar test, than a clear soap solution containing the same content of tar acids? I do

not suggest in this case that it is due to a higher wetting power, although a high wetting power in a disinfectant is very desirable so that it may thoroughly wet the surfaces which it is intended to disinfect, and, as we have seen, a good emulsion is a visible indication of high wetting power. I think that Chick and Martin's² explanation of the superiority of an emulsified disinfectant is correct, viz., that the bacteria are adsorbed on to the fine emulsified particles of the tar acid, and are thus brought into direct contact with the germicidal agent in a highly concentrated form. And, if this be the case, the larger the surface of tar acid exposed, the more highly efficient will be the disinfectant; or in other words, the globules of emulsified oil must be made as small as possible. The lower the interfacial tension between the solution of soap and the tar acids used, the finer will be the emulsion.

An almost identical problem is offered by the use of Twitchell's reagent for the saponification of fats. Twitchell's reagent owes its efficacy to its great emulsifying power, whereby the fat is broken up into innumerable fine globules, so that as large a surface as possible is exposed to hydrolysis. It might easily be determined if the reagent is up to standard and if it is the most suitable form for the particular kind of fat in use by a determination of the interfacial tension of solutions of the reagent and the fat, although I have never determined such myself.

Sometimes problems of the opposite character are encountered, where it is the object to avoid the formation of emulsions. The use of oil in turbines is a case in point. Some time ago it occurred to me that the drop pipette might be employed in this connection also, as an oil with as high an interfacial tension as possible would be the most suitable for turbine work. One of the large oil companies was good enough to supply me with a dozen specimens of oil, some of which were known to be unsuitable and some suitable for turbine work. I graded them according to their interfacial tension towards water, and in only two cases was I in error. I believe that if, instead of carrying out the determination of the interfacial tensions at ordinary temperatures, I had worked at one more nearly approaching working conditions these two discrepancies might have been avoided.

In every process in which any liquid is applied to a solid surface the question of wetting must play some part. Take the case of the application of contact poisons as a means of eradicating or at least controlling insect parasites. In various parts of the world ticks cause an enormous annual loss to cattle breeders. The usual means of dealing with ticks is by dipping the cattle in a dilute solution of sodium arsenite, but in the case of the "bont tick" it was found that the concentration necessary to kill the tick frequently led to the destruction of the cattle through bad scalding. By incorporating an oil emulsion with the dip, and thus ensuring a high wetting power, Cooper showed that it was possible materially to reduce the arsenic content of the dip and yet ensure the destruction of the tick without injury to the cattle. This application of wetting power alone has been instrumental in clearing large tracks of tick-infested country in various parts of the world.

Wetting power is of equal importance with all forms of tree and horticultural sprays as well as with insecticides. The obvious necessity of a contact poison is that it shall come into contact with that which it is intended to kill. And there is no real contact unless there is real wetting. The leaf of a tree is not an easy thing to wet; the chitinous integument of an insect is still more difficult; and the protective woolly secretion of the aphids of

American blight most difficult of all. Everyone knows that an emulsion of paraffin in soap makes a very fair tree spray, but perhaps few realise that the mixture owes its efficacy to the high wetting power conferred by the soap. Such an emulsion, however, usually fails to subdue American blight, either because its wetting power is not sufficiently high or because it lacks sufficient solvent action on the woolly secretions of the aphids. If such secretions are touched with a drop of alcohol, which possesses both wetting power and solvent action, the pest quickly succumbs.

For the valuation of soaps for technical purposes we usually rely upon a determination of the fatty acid content, and make no attempt to differentiate between different kinds of fatty acids, although experience often shows that certain fatty acids are more suitable for some purposes than for others. I would suggest that the drop pipette might also be used for determining the detergent action of different kinds of soap under the particular conditions in which they are used. We have already seen that the detergent action of soap is largely determined by its power of displacing grease and other matter from a surface, by virtue of the fact that the interfacial tension between the surface and the soap solution is less than the interfacial tension between the greasy matter and the surface. Thus, generally speaking, the detergent action of a soap is inversely proportional to its interfacial tension towards an oil.

In the varnish and paint industry interfacial tension also plays some part. When certain varnishes are applied to paper the interfacial tension of the thickening varnish towards the paper is so high that as the spirit evaporates the original film breaks and the varnish is drawn into drops. Much the same effect is produced by painting on a wet surface. Lack of attention to interfacial tension effects in the doping of aeroplane wings led to serious accidents in the early days of the industry. Acetylcellulose dopes are generally made up with a solvent which is not miscible with water. Cotton naturally contains over 7% of water, and its surface is undoubtedly coated with a fine film of moisture. Since an organic solvent would have little or no solvent action on this superficial layer of moisture, the dope would be unable to penetrate to the surface of the cotton itself; there would be no real wetting, no real contact, and so no good adhesion. It is not surprising therefore to find that dope applied under such conditions showed a great tendency to strip off in large sheets. Later, when care was taken to dry the cotton before applying the dope, there was perfect adhesion.

With the advent of the modern form of gas mask means had to be taken to prevent the deposition of moisture in globular form from the eyes and face on to the eye-pieces of the mask, which would impair vision. From what has been said it is obvious that all that is required is a substance which has a low interfacial tension towards glass or celluloid; the application of such would cause any moisture to be deposited in an even film, so that there would be little or no interference with vision. Much work was done on the subject by the Americans, and it is interesting to note that attempts were made to compare the efficacy of various "anti-dimming" compositions by determinations of their surface tension, with not always very gratifying results.*

Such are some of the more obvious applications of wetting power. Doubtless many more could be discovered, but perhaps these will suffice to show that the wetting power and interfacial tension are factors well worthy of the attention of the practical man, for they play no small part in many branches of industry, widely diverse in character.

Meeting held at Grand Hotel on December 6, 1919.

MR. JOHN ALLAN IN THE CHAIR.

A METHOD OF DETERMINING THE RELATIVE TEMPERATURES OF SPONTANEOUS IGNITION OF SOLID FUELS.

BY F. S. SINNATT, M.B.E., M.SC. (TECH.), F.I.C., AND
BURROWS MOORE, M.B.C. (TECH.) B.SC. (ENG.) A.I.C.

The investigation was designed for the purpose of obtaining information of the relative spontaneous inflammabilities of certain finely divided fuels, and to examine the influence of physical and chemical variations of the fuels upon the temperature of ignition.

The conditions under which the experiments were carried out were considered to approximate to the treatment received by fuels previous to combustion in a stream of air, when used for pulverised fuels. It seems possible, however, that the temperatures recorded may also be of interest in the study of those properties of coal which lead to ignition when brought into heaps, either in the mine, or during storage. With the exception of the method designed by Wheeler (Chem. Soc. Trans., 1918, 113, 945), no very clear indication can be obtained by means of tests of the liability of coals to undergo heating, either during storage or in the gowf. It will be seen that if pulverised fuels are to be widely used, it is desirable to have a rapid method available for measuring the relative ease with which the fuels will ignite. Upon this property the completeness of the combustion in a given space will depend largely, and also the degree to which the air can be pre-heated without the danger of pre-ignition occurring.

Fig. 1.

It appeared of interest to attempt to elaborate a simple means, necessarily empirical, by which some information upon this intricate subject might be gained, and, although the investigation is still

proceeding, we feel that the results obtained warrant our bringing them forward at the present stage.

It is not our intention to enter into a discussion of the literature of this subject; comparatively few experimenters deal directly with the temperature of spontaneous ignition of coal, and we are only able to find a few papers which actually deal with the determination, one of the most valuable being that of Wheeler. There is, however, a very wide literature dealing with the chemical aspect of the oxidation of coal.

The experiments to be described were planned (a) to determine the relative tendencies to spontaneous ignition in oxygen of certain finely powdered fuels; (b) to examine the influence of the degree of fineness of the particles on the temperature recorded; (c) to examine broadly the influence of the volatile matter upon the temperature recorded. For the purposes of this paper, the temperature of spontaneous ignition in oxygen is defined as that temperature to which a fuel must be raised for ignition to take place without the aid of external agents of inflammation.

Fig. 2.

The apparatus used for the experiments was similar to the ignition meter designed by Harold Moore, and successfully used by him to determine the relative ignition temperatures of liquid fuels (this J., 1917, 109).

The apparatus consists of a heavy cast iron vessel, in which an enclosed nickel crucible may be raised to any desired temperature. It is shown in section in Fig. 1. Fig. 2 shows the arrangement used by us, in which the apparatus is contained in an asbestos-lined box to eliminate the influence of draughts. The oxygen or other gas, before entering the nickel combustion chamber, traverses the U-shaped tube, bored into the casting. The length of this pre-heating tube is sufficient to raise the temperature of the oxygen to that of the casting, before it comes into the combustion chamber. A thermometer is placed in a cylindrical chamber, so arranged that the mercury is practically directly below the combustion chamber. The casting is deeply grooved at the bottom, in order to increase the surface exposed to the flame of a large bunsen burner, which is used as the source of heat. The oxygen was dried by passing it through concentra-

ted sulphuric acid. In certain experiments nitrogen was needed to sweep out the crucible, and a three-way tap was attached to the ignition meter, so that nitrogen or oxygen could be passed into the combustion chamber as required. Throughout the experiments, the oxygen was supplied to the instrument at the rate of three bubbles per second, as measured over a period of 60 seconds.

Preliminary experiments indicated that approximate constancy in the weight of the charge of fuel was necessary in order to secure reliable comparisons, and it was therefore decided to introduce the fuel into the combustion chamber from a "dropper" made of glass tubing, 8 in. long and $\frac{1}{4}$ in. internal diameter, with one end bent at right angles. The most suitable shape of cup was found by experiment to have a diameter about $\frac{1}{4}$ in., and depth about $\frac{1}{2}$ in. The cup was filled by dipping it into pulverised fuel, the sharp edge of a spatula was then drawn across the ground edges, and any loose particles adhering to the outside removed. With solid fuels, sifted through a certain size of mesh under similar conditions, the volume contained in the cup is approximately the same. Each of the samples of dust examined was examined microscopically, and, with the exception of the Irish peat and the Fusain, particles which have passed through the same size of sieve were found to have approximately the same size.

The weight of fuel contained in the cup was ascertained for two widely different types of coal, namely, Wigan Arley coal and Hoo canal coal. With Arley coal (graded to pass through a 1/200 sieve), the average weight of coal contained in the cup of the dropper for 14 determinations was 0.0052 grm., the greatest weight recorded was 0.0054 grm., and the lowest 0.0050 grm. With Hoo canal coal, similarly graded, the corresponding figures were 0.0057, 0.0061, and 0.0055 grm. respectively. It will be observed that the weight contained in the cup is fairly constant, although it cannot be considered free from error. An actual experiment was carried out in the following manner: The temperature of the ignition meter was raised until the reading of the thermometer was constant and the flow of oxygen exactly three bubbles per second. A charge of coal from the dropper was then introduced into the crucible, and a time record was kept of the following phenomena: (1) Commencement of visible active combustion; the mass glows. (2) Ignition, as manifested by an explosion or production of flame. (3) Extinction of visible combustion.

The especial points noted were the time interval before visible combustion or glowing occurs and the time interval before explosive or inflammatory ignition occurs. The progress of the combustion was watched through the central hole in the lid, and the residue, after visible combustion had ceased, was examined preparatory to the introduction of a fresh charge.

When a determination was complete the delivery tube for oxygen was detached, the lid covering the combustion chamber unscrewed, and the nickel crucible taken out, and its contents removed. Thus, for each determination the rate of supply of oxygen and the condition of the combustion chamber were appreciably the same.

The coals examined were: Wigan Arley coal, Wigan Yard, anthracite, Hoo canal (26% ash), and two coals liable to produce gob fires (Nos. 1 and 2).

The coal was pulverised so as to pass through a 1/200 mesh sieve and was air-dried; the samples, with the exception of Hoo canal, were fairly freshly mined, *e.g.* not mined longer than three weeks. The results are shown in the following tables:—

The above values are plotted in the graphs, figs. 3—8.

The following is a brief analysis of the above results:—

In all the cases, except at the higher temperatures, glowing in the mass of coal commences before ignition takes place, and the time interval before the former occurs decreases with rise in temperature. The variation of the "time intervals" before ignition takes place, compared with the intervals for glowing to appear, are somewhat irregular. There is a well-defined temperature below which no glowing occurs within a time limit

Fig. 3.—Glowing.

Fig. 4.—Ignition.

Fig. 5.—Arley.

of four minutes, and, with the exception of Hoo canal, this also applies to the ignition. In the case of Hoo canal (which contains 26% of ash) an intermediate range of temperature exists, at which no active ignition occurs.

In the coals examined, with the exception of the two which are known to be liable to gob fires, there appear to be zones of temperature at which spontaneous ignition occurs after a much longer interval, and it would appear that coal yields volatile compounds at these ranges of temperature, which compounds have a higher temperature of ignition (compare figs. 3 and 4). It is suggested that such coals may possess the property at these temperatures of tending to extinguish any heating which may be taking place, especially where the coal is in masses, and the oxygen only in contact with the surface. Where, however, coal does not evolve such compounds, no such self-damping action is possible, and the result of the oxidation would be an additive one consisting of glowing of the solid substances, and ignition of the volatile constituents. This feature of the work requires more exhaustive examination.

Fig. 6.—Yard coal.

Fig. 7.—Anthracite.

Fig. 8.—Coal liable to gob fires, No. 2.

It will be noticed that in the case of the two coals liable to gob fires, the curves of spontaneous glowing and ignition are practically parallel (compare figs. 3, 4, and 8), but there were very clear

evidences of the spontaneous ignition occurring practically at the same interval at which the glow was visible; in other words, the volatile compounds produced from these coals were more easily inflammable than was the case with the other coals examined.

In order to obtain an idea of the minimum temperature at which substances would either glow or ignite, a time limit of four minutes was adopted, and the lowest temperature at which substances would glow or ignite within this period was taken as the temperature of glowing or ignition. The time interval was decided upon as being sufficiently long for most practical purposes.

The values obtained for a number of substances are given below:—

Substance.	Minimum temperatures in oxygen, °C.

Influence of the degree of fineness of the particles of the coal upon the minimum temperature at which spontaneous glowing occurs.

Early in the experiments it was found that the degree of fineness of the fuel had a considerable influence upon the minimum temperature at which spontaneous glowing would occur, and preliminary observations have been made to ascertain broadly the influence of the degree of fineness of the fuels examined. The results are recognised as being quite preliminary, but as they show that the degree of fineness is a most potent factor, it is desirable to place them on record at once.

Minimum temperature at which spontaneous glowing occurs.

Coal liable to gob fires, No. 1	232	346	—
Do, do, No. 2	225	298	—

It will be observed that coal pulverised to pass through a 1/100 to 1/200 mesh sieve did not commence to glow at a temperature below about 400° C. within four minutes, whereas, when pulverised to pass through a 1/200 mesh sieve, glowing commenced at a much lower temperature. Further, that mixtures of fine and coarse material appear to commence to glow at a temperature approximating more closely to the glowing temperature of fine material than to that of the coarse material.

The influence of the volatile matter present in the fuel upon the temperature at which spontaneous ignition occurs.

The results recorded up to the present indicate that the inflammatory or explosive ignitions which coincide with, or follow, the initial glowing of the fuel, are associated to a degree with the volatile matter present in the fuel. It was therefore thought desirable to place on record some experiments we have commenced upon the influence of the volatile matter upon the liability of the fuel to glow or ignite spontaneously. It was thought that if a charge of fuel could be maintained at a fixed temperature in the crucible, under conditions which would simultaneously preclude the oxidation and assist the expulsion of the volatile matter, and the residual material at once examined to determine the temperature of spontaneous inflammation and glowing, that the resulting observations might be compared with those obtained by a blank experiment, using oxygen alone at the same temperature. The apparatus was therefore arranged so that nitrogen could be passed into the combustion crucible, and by merely reversing the three-way tap a supply of oxygen could be at once introduced. The nitrogen used was freed from oxygen by passing it through two bottles containing alkaline pyrogallie acid, and the rate of flow was six bubbles per second. The nitrogen was passed in at this rate in order to have a distinct sweeping action and yet not disturb the charge in the crucible. The ignition meter was raised to any required temperature, the nitrogen turned on, and a charge of coal introduced from the dropper. The coal was kept for 15 minutes in the supply of nitrogen. At the end of the period determined upon the supply of nitrogen was interrupted and oxygen introduced into the crucible at three bubbles per second. The time interval before glowing or ignition occurred was then determined. The crucible was at once emptied from any residue, and a fresh charge or blank was dropped into it, having the oxygen continually flowing. The process was repeated for different temperatures, and the results are given in the following table:—

the fuels (except Hoo canal) which had been previously exposed to nitrogen failed subsequently to glow or ignite in oxygen within the time interval of four minutes, whereas the control samples examined immediately afterwards behaved exactly as we have previously recorded. In the case of Hoo canal, glowing and sometimes ignition was observed for the charges exposed to nitrogen at temperatures of 330° to 380° C., i.e., considerably above the minimum temperatures previously recorded. In all cases the actual ignition which occurred was of a less inflammatory or explosive character when the coals had been heated in nitrogen.

The conclusion to be deduced from these observations is that the volatile matter of the coal has a considerable influence upon the liability of the fuel to glow. The non-appearance of glowing in the case of the nitrogen-treated charges appears especially important where the material has only been heated to temperatures not appreciably above the minimum temperatures previously recorded for glowing to occur, and it would therefore appear that the oxidation of the volatile constituents evolved contributes very largely to the heating effect, which leads to the mass of coal becoming heated, and consequently to the production of a glow.

We wish to suggest that the minimum temperature for glowing to occur in coals may be of use in comparing the relative ease with which coal will undergo oxidation. It is our intention to examine coals which are liable to undergo ignition during storage, and others which produce gob fires. It seems possible that the curves indicating the time interval at which coals will glow at different temperatures may be a means for characterising coals. Further, the experiments have afforded direct evidence that fineness of the material has an influence upon the tendency to spontaneous ignition and glowing, and that if the particles are present in sufficient proportions the temperature at which the mass will glow is determined largely by the proportion of the fine material present. The

Air-dried sample.	Exposed to nitrogen for 15 mins. before admission of oxygen.			Temp., °C.	No previous exposure to nitrogen before admission of oxygen.

		No glowing.	370	10		

It may be observed that at temperatures only slightly above the minimum temperatures previously recorded for the occurrence of glowing, all

results also indicate that the volatile constituents evolved at any particular temperature have a considerable influence upon the temperature at which

spontaneous glowing occurs. The work is being continued along a number of lines.

We have to thank Miss P. Wray for help during the final preparation of this paper, and are indebted to the Lancashire and Cheshire Coal Research Association for supplying us with the samples of coal used in the work.

DISCUSSION.

MR. J. DRUMMOND PATON said that if reference was made to the work done by Mr. Lomax and himself (the speaker) it would be found that a solution for certain of Captain Sinnatt's curves was already provided by an examination of the halations of the volatile constituents as manifested in photomicrographs. The various agents from which these halations were obtained had already been stated, and the three peaks on the curve shown were dependent upon three regions from which the volatile matter was evolved, namely, the paraffinic, the cresylic, and benzenoidal. An examination of the oxidation effected and the ignition temperatures of the gases evolved and the sources of production would probably suggest many reasons for the glow and the explosive effects. It was well known that in gob coals, or coals which created gob fires, these effects were usually accompanied by a high percentage of oxygen, and this was necessarily the first source of supply for spontaneous ignition. With regard to the damping-down effect, it was well known also that any of the constituents mentioned could be emitted from a coal on a red-hot bed without being ignited, this being dependent upon the rate of emission of the same gases. The structure of coal, as shown by photomicrographs, very often explained the rate of emission, and the halation and colour effect would also define the zone in which they existed and the temperature at which they would be emitted. A damp or saturated hydrocarbon gas would not ignite in an atmosphere where it was in excess, and especially in regions and atmospheres with a large amount of vapour or steam accompanying the emission of the hydrocarbon.

MR. GIBSON asked whether the same time was taken in connection with the coarse material and whether the method of grinding and pressure were identical; also whether the same sieves had been used, whether they were standard gauze, and whether the method of sifting was standardised. The degree of coarseness of the coal was extremely important. He suggested the advisability of tests to ascertain whether the fineness or coarseness agreed by using a totally different method.

MR. W. PAYMAN suggested that instead of leaving the coal at the bottom of the crucible it might be permitted to fall through the hot gas. Gases evolved from the dust were not always present in dust explosions, these being obtainable with charcoal. With coal that was falling through a gas mixture it might be possible that ignition would take place at a much different temperature. In the case of coal burning in air in any type of industrial burner there was quite an efficient mixture of the coal dust and the air. He thought there was not such a free access of oxygen to a gob fire when it was starting as there was in the case of the experiments under review.

MR. TIDSWELL asked whether the absence of glowing, observed with certain coals after previous treatment in nitrogen, could not be more easily explained by the changed state of the coal after heat treatment, reducing its capacity for absorption of oxygen, rather than by the assumption that the glowing was caused by the combustion of the volatile decomposition products of the coal.

DR. H. F. COWARD said that, so far as he was aware, no other serious attack on the present problem had been attempted. The most severe

criticism he could make was that the authors were not measuring the ignition temperature of coal; they were measuring the ignition temperature, in the defined circumstances, of the most inflammable portion of the contents of the vessel, and these consisted of gas, vapour, and partially carbonised coal. The measurement of the ignition temperature of coal itself was an extremely difficult problem. Coal underwent slow exothermic oxidation in contact with air at low temperatures, and if it were contained in an enclosure the heat conductivity of the walls of which was zero, the coal must ultimately inflame. That was an extreme case unattainable experimentally, and in practice a compromise had been adopted in the definition of the ignition temperature as that temperature at and above which very rapid self-heating occurred in the reacting mixture, so that inflammation was observed within a small fraction of a second after the materials had been brought to that temperature. The authors had not been observing this, but they had been determining another very important constant connected with the decomposition and ignition of coal, and this might perhaps be better described by another name than ignition temperature, but it would lose none of its significance thereby. He (the speaker) had just used the word "constant," which he understood from Mr. Sinnatt was applicable if the standard apparatus were used in the standard way. In addition to those details of standardisation mentioned by the authors, they would perhaps find that other observers using exactly the same methods would get different results for one and the same coal, even if each used sieves of the same nominal size for grading the coal. The fineness of the sifted coal depended on the dimensions of the spaces between the wires, and these were governed by the diameters of the wires themselves, as well as by the number of wires per inch.

CAPT. SINNATT said that it was intended to examine the effect of the chemical composition of the coal upon the results, and it would be necessary to include an examination of the structure of the coal as indicated by the microscope. As the method was empirical in character, every detail was carried out under similar conditions, the same sieves and manner of grinding and sifting were used throughout the experiments. The coal used was freshly mined and the moisture present was standardised. In one case a sample of coal (Arley) was exposed to the air for three months in a fine state of division and then tested, when values much higher than those given by the freshly mined coal were obtained. Until further evidence had been brought together it was difficult to explain the increase in temperature of glow and ignition found after heating the coal in nitrogen in view of the fact that the temperature to which the coal was heated never exceeded about 350° C. When two points were found on the ignition curve two explosions had occurred. Their object in devising the test had been to keep the apparatus and method of manipulation as simple as possible, as, in their opinion, the determination of the temperature of glow (and of ignition) must in its essentials remain an empirical one until our knowledge of the constitution of coal is much more extensive than it is at present.

MR. HAROLD MOORE, referring to tests made by himself when designing the instrument, said that it was surprising how little the results were affected by such variations as halving or doubling the quantity of the charge put in, using from one quarter to four times the normal quantity of oxygen per unit of time, and also by the catalytic effect of the surface of the ignition chamber. The original crucible was made of platinum, while later on porcelain, silica, aluminium, copper, and other crucibles were used. In no case did the variation exceed 2° on

the ignition readings when the readings were somewhat about 300°C ., so that, though the test was empirical, there was something to be said in favour of that type of apparatus. He thought the peaks on Captain Sinnatt's curves could be explained by the generation of certain hydrocarbons or other organic compounds. The simple hydrocarbons, methane, ethane, and so on, had considerably higher ignition temperatures than the temperatures at which Captain Sinnatt was working, and might "blew out" the flame or "dilute down" the oxygen mixture until there was such a low concentration that the ignition point was raised. Incidentally, it could be expected that dilution of the oxygen from 100% down to 50% would greatly affect the result. During the course of experiments with aircraft engines, in which the exhaust gases were being trapped in the cylinder in order to raise the ignition point of the mixture, a certain number of tests were made, and he was surprised to find that on diluting the oxygen from 98% to 30% or 40% the ignition point was only affected about 2°C . The carbon dioxide was in these experiments supposed to represent the exhaust gas. Experiments conducted in air gave much less regular results. The ignition point of a mixture of two volatile compounds was a much more complex matter than might appear at first sight.

Meeting held at Grand Hotel on January 9, 1919.

MR. JOHN ALLAN IN THE CHAIR.

A NEW INSTRUMENT FOR MEASURING VAPOUR TENSION.

BY HAROLD MOORE, M.SC.TECH.

The determination of the volatility of motor spirit has hitherto been carried out by fractional distillation, but this test is only an indirect indication of the behaviour of the spirit in the engine. In the jet carburettor of the present day the ratio between the amounts of fuel in the liquid and in the gaseous state determines the ease of starting under standard conditions, and the "flexibility" of the engine whilst running at varying loads and speeds.

The proportion of fuel volatilised is dependent upon the vapour tension of the fuel, and the vapour pressure also requires to be determined in the valuation of motor spirits. The standard method of determining vapour pressures of liquids is by means of a barometer enclosed in a water jacket to enable the temperature to be regulated. The liquid to be tested is introduced under the lower end of the barometer tube by means of a pipette, the end of which has been bent. The fall in the mercury column after equilibrium has been established gives the vapour pressure at the temperature of the experiment.

This method is accurate and reliable and is most suitable when a very low degree of experimental error is essential. It is, however, very tedious to clean out and re-assemble the apparatus, and for this reason the method has not found use in technical work. Redwood and Thomsen devised a simple form of instrument for gauging the relative vapour pressures of motor spirits,* but this does not give true vapour pressure readings.

After experiments with various types of instrument, one of which is described in the "Automobile Engineer" of September and October, 1918, the author devised the apparatus shown in the accom-

panying figure. This consists of two tubes of about $\frac{1}{2}$ in. bore and about 800 mm. long, connected to each other and to a levelling bottle by means of a Y-piece and thick-walled rubber tubing. The two tubes are clamped in a vertical position and have mercury-sealed cocks at their upper extremities. One of the tubes is surrounded by a water jacket in which a thermometer is suspended.

Fig 1.

When the levelling bottle is raised, the two cocks opened, and mercury flooded into the cups attached to the cocks, and then the cocks closed and the levelling bottle sufficiently lowered, two barometers are formed. The method of making a determination is as follows: One cup is filled with motor spirit; a small amount (measured by a mark below the cock) is passed into the tube, and sufficient mercury afterwards placed in the cup to ensure an effective seal. The levelling bottle is then lowered, when the barometric height may be read from the empty tube, whilst the jacketed tube containing the motor spirit gives a reading which is the barometric height minus the vapour pressure of the motor spirit at the temperature of the experiment. The difference in height between the two tubes is the vapour pressure reading. It is necessary for accurate readings to make a correction for the density of the mercury, but on the motor spirit tests in question this was not done, as the quantity was

* See V B Lowes, J. Soc. Arts, 1915, 63, 760.

considerably less than the normal experimental error.

When it is necessary to make a trial of a new substance the tube is best cleaned by repeated washing with the substance about to be tested. After each wash the mixture is removed by flooding it into the cup and absorbing in filter paper. Where two substances are insoluble in each other the washing method may be modified by the use of an intermediate substance which is soluble in both.

Fig. 2.

Fig. 3.

The vapour pressure increases with rise of temperature, and the results are best shown in the form of a graph, in which temperature and vapour pressure are the components.

The laws governing vapour pressures of mixed substances are somewhat complex, and a mixture of two soluble substances is liable to give a vapour pressure either lower than that of either constituent, or greater than that of either constituent, and may approach the sum of the vapour pressures of the substances at the given temperature. Cases in which the latter phenomenon is shown are of ex-

treme importance to the student of motor fuels, as any method of raising vapour pressure is of great value. In cases where the vapour pressure exceeds the necessary value there may be found plenty of cheap fuels which can be added to bring about the necessary reduction in volatility.

From these considerations it was deemed advisable to work out the vapour pressures of mixtures of important fuels with varying compositions and at varying temperatures. The temperature was controlled by passing the water through a heating coil before it entered the jacket until a temperature slightly in excess of that desired for the highest reading had been attained. The current was then discontinued and the readings taken as the apparatus slowly cooled.

Fig. 4.

The vapour pressure/temperature graphs for benzene (crystallisable), petrol (Pratt's "Perfection"), and alcohol are shown in Fig. 2. The diagram for mixtures of 98% alcohol with benzene (crystallisable) at various temperatures is shown in Fig. 3, the vapour pressure being plotted against composition. Similar curves for alcohol-petrol mixtures have been prepared, and the results are shown in the curve in Fig. 4.

The experimental error when making determinations on water was only about 3 mm., but with these mixed motor spirits the error is undoubtedly much greater. In mixtures containing petrol a slight amount of gas is formed, which is not re-absorbed by increasing the pressure. This gas cannot be formed by leakage of the cocks, as it forms within one minute of taking readings, whereas the apparatus can be left charged under vacuum for many hours without any leakage becoming apparent. The results have not the degree of accuracy which is desirable for this class of work, but the essential point was to find the direction of the curves of pressures for various mixtures, and the general tendency is clearly indicated in the graphs.

DISCUSSION.

MR. MORTON said in regard to the permanent gas dissolved that he had found it necessary to take two

readings on a barometer tube—one where the liquid was at the top of the tube and one where it was at the bottom. The amount of gas dissolved could then be calculated when dealing with a pure substance. To obviate errors due to dissolved air, some of the liquid should be introduced into the barometer tube and the mercury lowered until it was at the bottom of the barometer tube and most of the dissolved air had been released; the liquid and the mercury should then be made to rise rapidly and a small amount of the liquor allowed to pass through the top, when the cock should be closed. A repetition of this procedure would remove all dissolved air. He asked how the difficulty in regard to grease on the stopcocks was overcome. He had had to devise an apparatus without stopcocks. In most of the determinations the chief difficulties were caused by the amount of dissolved air always present in any liquid and by using too small an amount of liquid for the estimation.

MR. GIBSON said that the approximately straight-line petrol graph did not agree with results he had obtained within the past few months, using an ordinary tube method, dealing with a petrol containing in some cases 5% of very light volatile constituent, and up to 20, 30, and 40%. The stopcock question was a difficult one. What guarantee was there that no leakages or evaporation occurred with very light constituents?

CAPTAIN F. S. SINNATT asked if the effect of naphthalene upon the vapour pressure of motor spirits had been tested. What was the effect of a small quantity of heavy or high boiling material upon the curves obtained?

MR. MOORE, in reply, said he had entertained the opinion that the gas formed was natural gas in solution. It was quite possible, even if compressed natural gas had not been used in the mixture to make up the motor spirit (which he did not think was so in the case of Perfection spirit), that some natural dissolved gas might come through in the distillation process. He had not analysed the gas itself. He had tried to remove the gas by subjecting the spirit to a vacuum and then blowing it out afterwards, and certainly after the gas was once removed no more was formed. When a small bead of gas was left in the top, if the mercury were raised a little higher and the gas blown out sufficient liquid was left in the tube to give a reading, and no gas would be formed. He questioned, however, whether such a course was permissible, since it was desired to test the spirit as it actually existed. A similar curve with a slightly higher vapour pressure was obtained if the gas was not extracted. The stopcocks were sealed with mercury, and even if the apparatus were left for four or five hours there was less than $\frac{1}{2}$ mm. loss. When the cocks had been well ground in, even after the lapse of a month, the leakage was mercury leakage and not air leakage. A small quantity of a very volatile constituent raised the vapour pressure a great deal. The measurements of level were taken by a rule placed directly behind; there was no necessity to use measuring instruments, as most of the experimental error was much greater than the error in actually reading the columns. He had not prepared curves in the case of naphthalene mixtures. The vapour pressures of naphthalene itself had been published in Schnitz's book on liquid fuels. A small quantity of heavy substance did not appear to affect the readings appreciably. Evaporation did not affect the results once the instrument was filled. In his experiments the material was only exposed for 10 to 30 seconds prior to the beginning of the experiment. The duration of the actual experiment was three hours. During the whole of that time no more of the volatile liquid was taken from the upper cup into the tube, it acting only as a seal.

MR. F. H. CARR IN THE CHAIR.

NOTE ON THE REICHERT-MEISSEL-POLENSKE METHOD.

BY H. DROOP RICHMOND, F.I.C., AND G. F. HALL, M.B.E.

The directions given by Polenske (*Z. Unters. Nahr. Genussm.*, 1904, 7, 273; this J., 1904, 387) are very explicit and appear to be adhered to generally, but in two respects analysts are prone to introduce slight modifications, *i.e.*, in the time of distillation and the temperature to which the water in which the flask containing the distillate is cooled. Indeed it appears general to depart from Polenske's prescribed temperature of 10° C., and most of the text-books give 15° C. as the temperature of cooling. Both these points have been investigated. The samples of coconut oil used in the two series were not identical.

Experiments on time of distillation.

Substance.	Time.	Soluble acids.	Insoluble acids.
	Mins.		
Butter	19½	31.0	2.25
"	20½	32.05	2.4
"	38½	32.0	2.35
Coconut oil ..	20	8.45	18.3
"	20½	8.3	17.9
"	24½	8.5	17.55
"	27	8.45	16.9
"	36	8.35	16.45

It is seen that with butter the time of distillation does not greatly matter, but with coconut oil it is essential to adhere to Polenske's directions (18 to 22 minutes).

Experiments on temperature.—Coconut oil.

Time of distillation. Mins.	Temperature of cooling. ° C.	Soluble acids.	Insoluble acids.
21	5	8.3	16.4
18½	10	8.0	16.6
20	10	8.5	16.0
20	10	8.5	16.4
19	15	8.5	16.1
20½	15	8.55	16.1
20	20	8.5	16.2

It is seen that the temperature to which the distillate is cooled does not greatly affect the results.

This work was done in the Analytical Laboratory of Messrs. Boots Pure Drug Co., Ltd., to whom our thanks are due.

SODIUM PEROXIDE FUSIONS.

A. E. MUSGRAVE.

When using the Roland Wild calorimeter the estimation of sulphur may be conveniently combined with that of the calorific value of the fuel. In many cases, however—as, for instance, foundry coke—it is desirable to estimate the percentage of sulphur without determining the calorific value. For this purpose—sulphur estimation—the Roland Wild calorimeter is unwise, as the top of the crucible is attached to the top and stirring gear of the calorimeter vessel. A very simple and convenient crucible cover was therefore made, so that

the crucible may be much more easily handled when carrying out sodium peroxide fusions with solid fuels and other substances.

The crucible and cover are shown in the illustrations. The crucible is of nickel; both cover and tube are of brass; ignition is effected by dropping down the tube a piece of red-hot nickel wire about 10 mm. long and 1.25 mm. diameter (17 to 19 gauge). The crucible top may be screwed down tightly on the rubber gasket, and the whole crucible immersed in a beaker of cold water to about 1 in. above the top of the crucible. If it is feared that any sulphur contamination may result from the rubber gasket (which has not been found to happen) this may be avoided by omitting the rubber gasket, screwing the top on the crucible and immersing the latter in the cold water to within about 3 mm. of the crucible top, then igniting, etc., as previously described.

The melt always leaves the crucible cleanly, and after several hundred fusions the crucible and cover appear as good as new. The brass tube in the crucible cover is 185 mm. long, 9.5 mm. diameter, and 7.5 mm. bore. It will be noticed that there is no trap at the top; this facilitates the introduction of the red-hot nickel wire, and the loss by spurting is negligible.

Communication.

A NEW TEST FOR THE DETECTION OF LIGNEOUS IMPURITIES IN COTTON AND COTTON WASTE FOR NITRATION PURPOSES.

BY FRANK LESLIE BARRETT.

The older method of detecting woody impurities in cotton to be used for making nitrocellulose, con-

sists in dyeing samples of the material with a basic dye, when these impurities appear as deeply dyed specks on a coloured background. This is known as the "dye test," and unevenness of dyeing is ascribed to the presence of oxycellulose in the fibres. The dye solution employed is sufficiently strong, however, to colour the fibres deeply, and the detection of the ligneous matter is thereby rendered more difficult.

The usual method of carrying out this test is to boil 2 grms. of the cotton with 100 c.c. of a 0.2% solution of rosaniline hydrochloride, and then to heat the material with repeated changes of water until the wash water is free from dye. The complete removal of the loose dyestuff from the fibre is difficult, and the test is therefore unsatisfactory as a means of detecting oxycellulose.

In investigating the efficiency of the dye test several cotton wastes cleansed by different processes were examined, and it was found that where small traces of certain impurities were present in the fibres, the cottons dyed to deep shades, whereas the soda solubility and copper values were normal. These impurities, which are probably phenolic in character, appear to act in a manner similar to that of the tannin compounds used in cotton dyeing, and assist in the fixation of the dye. When these cottons were deeply dyed, the detection of the woody impurity, which was only very slightly darker, was difficult. It was also found that the presence of local grease on the cotton causes uneven dyeing, and might be mistaken for oxycellulose.

Attempts were therefore made to devise a more satisfactory test for the presence of ligneous matter in cotton. A large number of experiments were made with various microscopical staining reagents for lignified matter. Such reagents as those suggested and discussed by E. Grandmougin,* Wheeler,† and Cross, Bevan and Briggs‡ were also tried and found to be unsuitable for the detection of woody matter in cotton waste by visual examination. These reagents included aniline, toluidines, xylydines, phenylenediamines, diphenylamine, naphthylamines, their various salts, methyl and nitro derivatives, phenols such as carbolic acid, cresols, dihydric and trihydric phenols, naphthols, and also nitro- and aminophenols. Attempts to develop Aniline Black on the ligneous matter were unsuccessful.

Attempts to make use of the specific reactivity of the lignone groups were therefore abandoned, and work was confined to the dyeing of the woody matter with basic dyes. It was found that Malachite Green, the oxalate or zinc double salt of tetramethyldiaminotriphenylcarbinol, is readily absorbed by woody matter. Endeavours were made to heighten the contrast between the dyed ligneous particles and the tinted cotton by the use of a second dye, Bismarck Brown, to counteract the green tint imparted to the cotton with production of a neutral shade, but such methods were rejected after extended trial.

Satisfactory contrast was obtained by treating the cotton waste dyed with Malachite Green with an oxidising agent, which immediately discharged the dye loosely held by the cotton fibres, whilst the retention of the colour by the particles of wood was more persistent. The addition of formaldehyde to the dye-bath assists the fixation of the Malachite Green by the ligneous matter, and the colour is not discharged by treatment with strong oxidising and reducing agents. Further, it was found that the colour could be conveniently discharged from the cotton by adding a solution of bleaching powder to the dye-bath in presence of a trace of acid.

* Z. Farben u. Textilchem., 1906, 5, 321-323.

† Ber., 1907, 40, 1883.

‡ Ber., 1907, 40, 3119.

Method of carrying out the test.—The dye solution is prepared by dissolving 0.1 gm. of pure recrystallised Malachite Green in hot distilled water or good tap water (about 100 c.c.), diluting to 500 c.c., adding 50 c.c. of 40% formaldehyde solution and 1 gm. of sodium bisulphate (NaHSO_3) dissolved in a little water, and making up to 1 litre.

The bleaching powder solution is made by shaking 20 grms. of bleaching powder (containing about 35–37% of available chlorine) with 1 litre of good tap water, allowing to stand, and pipetting off as required.

Dyeing is conveniently carried out in 500 c.c. porcelain beakers, eight of which can be heated in a convenient-sized bath and run in a series. 300 c.c. of dye solution is placed in each beaker. After the beakers have been heated in the water bath for a few minutes, 3-grm. samples of cotton are placed in each and allowed to remain in the dye liquor at the temperature of boiling water for 10 minutes, with occasional stirring. At the end of that time, 25 c.c. of the bleaching powder solution is added to each bath from a pipette, and after addition of the bleach solution the baths are stirred rapidly.

On addition of the bleaching solution the colour of the bath is immediately discharged. The cotton is allowed to remain in the hot liquor for a further 5 minutes; the liquor is then poured off, the cotton being used as a filter to catch any small particles of husk etc. The treated material is rinsed first with tap water and then with distilled water, and examined wet for green specks. It is important to use pure Malachite Green and to keep the baths well stirred during dyeing and bleaching.

Experimental.

Carded American cotton (good middling quality), which had been cleansed by boiling with caustic soda solution under pressure, was selected as a typical pure cotton. Samples of this material submitted to the test remained white. On careful examination minute specks of green-coloured woody matter could be detected occasionally in the samples.

Effect of typical ligneous impurities.—To investigate the efficiency of the test, a large number of experiments were made in which samples of the purified American cotton were adulterated with impurities commonly found in cotton waste, such as cotton husk, leaf and stalk, cotton seed, straw, including common cereal straw and the eastern grass used in packing bales, hemp and jute fibres, and teased fibres from the ordinary Hessian bale covers. These impurities were examined in the unboiled state and after they had been subjected to a pressure boil with caustic soda as in the ordinary process of cotton waste purification.

In every case the cotton remained perfectly white after treatment, whilst the impurity took the characteristic green colour and retained it. Where foreign vegetable impurity could not be detected by visual examination in the untreated materials, its presence was clearly disclosed by the test, the green dyed particles being very conspicuous on the white background, and on examination under the microscope particles of broken dyed fibre could be seen intermingled with the cotton.

Further experiments showed that, if the test is properly and carefully carried out, the dyed woody

material is not decolorised by prolonged exposure to the action of the bleach solution, and also that the test is unaffected by the presence of grease on the fibres.

Comparative tests on typical cotton wastes.—A large number of cotton wastes, purified by boiling with 2–4% caustic soda solution at different pressures, have been examined by the older dye test and by the test suggested above. The latter indicated the presence of the ligneous material much more clearly, and enabled a better discrimination to be made between the different samples. Thus, relatively large proportions of woody impurity were found in samples boiled at atmospheric pressure, somewhat less in samples boiled for short periods under low pressure, while samples boiled for 10 hours or more under pressure were found to be reasonably clean. As expected, cottons boiled at 80 lb. per sq. inch appeared to be more free from woody matter than those boiled at 40 lb., whilst those boiled at 40 lb. contained less ligneous impurity than those boiled at 20 lb. and at lower pressures. Again, materials boiled with 4% caustic soda appeared cleaner than those boiled with 2% caustic soda and 2% sodium carbonate.

Examination of a large number of cotton wastes prepared for nitro-cotton manufacture showed that in cases where the material had not been bleached the detection of the woody impurity was difficult in samples dyed with rosaniline hydrochloride on account of the original dark colour of the waste, whereas in samples dyed by the Malachite Green method the impurity was easily recognisable, as the dark shade disappeared on treating with the bleaching powder solution. When the particles were extremely small and unrecognisable by the routine test, they could easily be found by the modified method.

The test has been devised for the detection of woody impurity in cotton waste and not, of course, for the detection of oxycellulose. About 300 to 400 samples of wastes have been examined by the method, over 200 of these in comparison with the well-known rosaniline dye test, and in every case the former has been found to be much more discriminative. In no case could undyed woody matter be detected.

It has, for some time past, been employed as a routine test in a number of works and laboratories, and has been found to give excellent results.

It is desired to thank the Director of Artillery for permission to publish those results, Lieut.-Colonel R. A. Craig, C.M.G., R.A., and Sir R. Robertson, K.B.E., F.R.S., for facilities afforded in carrying out the experimental work, and Drs. W. H. Gibson and A. Forster for valuable suggestions made during the carrying out of the work, which formed part of an investigation undertaken at the Research Department of the Royal Arsenal, Woolwich.

MR. JOHN ALLAN IS THE CHAIR.

A NEW CHARACTERISTIC FOR COAL: THE AGGLUTINATING POWER CURVE.

BY F. S. SINNATT, M.B.E., M.Sc. (TECH.), F.I.C., AND
A. GROUNDS, B.Sc. (TECH.), A.I.C.

This work is part of the investigation of Lancashire coals being carried out under the auspices of the Lancashire and Cheshire Coal Research Association.

The present paper contains a study of the agglutinating power of coal under certain special conditions, and affords an auxiliary means for the identification and valuation of coals, with especial reference to their caking qualities. Although the test for the agglutinating power of coal has been studied fairly completely by certain firms for industrial purposes, the literature of the subject is somewhat scanty, the following being the two chief contributions: Campredon* describes a method for measuring the caking value of coals by heating a standard weight of coal with varying weights of inert matter (Calais sand) in a platinum or porcelain crucible. The test was repeated until the maximum amount of inert matter which could be sustained by a coal was found, the coal still yielding a coherent button of coke. J. T. Dunn† observed that, occasionally, coals of high ash value had given higher agglutinating values than coals of a similar nature but of low ash value, the latter coals being obviously much more suitable for the manufacture of coke. He found that much more consistent results could be obtained by the use of anthracite in place of sand as the inert matter. The coal to be tested was passed through a $\frac{1}{2}$ mm. sieve (approximately 1/50 sieve), whilst the anthracite was graded from 1 mm. to $\frac{1}{2}$ mm. (i.e., while it passed through a 1/25 sieve it would be retained by a 1/50 sieve). The proportion of the weight of inert matter to the weight of coal was taken as a measure of the agglutinating power. In the discussion which followed this paper it was suggested that retort carbon might be substituted for anthracite, and one speaker also mentioned that particular care should be taken to specify the size of the anthracite. Further, it was stated that the coking test should be carried out in a muffle, and not over a Bunsen burner, and that the period of carbonisation should be controlled. It was considered that some definite mechanical means should be adopted to measure the strength of the resulting coke.

No further attempt, as far as we are aware, has been made since the publication of the above paper to standardise a method for determining the caking value of coals.

The temperature at which the coking or caking determination is carried out is usually lower than that at which the ash of coal becomes fusible, but there is a possibility (as suggested by Dunn) that the inorganic substances present in the coal may fuse during the carbonisation. It is well known that certain coals contain ferrous carbonate, and if the temperature at which the test is carried out is high, slight slagging may occur between the sand and the inorganic constituents of the coal. It is therefore desirable to choose an inert material which has no agglutinating power, either when

heated alone, or when heated with coal. Further, a substance which does not give rise to the evolution of gaseous products is preferable, as these have a distinct influence upon the rate at which the volatile constituents of coal are eliminated from the sphere of the reacting mass. The greater the volume of gas evolved by the inert matter and the greater the proportion of the latter present, the shorter the period the volatile constituents are in contact with the coal during the carbonisation. For these reasons it is considered that sand and anthracite are not entirely suitable. As it is desirable to measure only the caking power derived from the decomposition of the organic compounds present in the coal, which bind together the coke formed during the carbonisation, the inert material should resemble coke as far as possible. The inert material should not be porous, or it tends to absorb the binding or agglutinating substances produced during the carbonisation of the coal, the effect of which will be lost. Further, the particles of the material chosen should be spheroidal in shape, thus eliminating binding together of the substance by interlacing of the particles, either alone or when mixed with the coal or coke. The substance finally chosen by us was pulverised electrode carbon, which appears to satisfy most of the above conditions. "Flame-arc" carbons should not be used, as these are impregnated with sodium and calcium salts, which might act as a flux for the ash of the coal, thus producing a binding effect and influencing the agglutinating value of the coal.

In order to study the influence of the degree of fineness of the powdered inert matter, a quantity of carefully graded electrode carbon was prepared; 14 lb. of electrode carbon was pulverised so as to pass through a 1/10-mesh sieve. It was then intimately mixed and carefully sampled and analysed, with the following results:—Moisture, 0.17%; volatile matter, nil; ash, 1.4%; carbon, 98.35%. This material was then sifted through the following tiers of sieves: 1/10 to 1/30; 1/30 to 1/60; 1/60 to 1/90; 1/90 to 1/120; 1/120 to 1/180; 1/180 to 1/200; and through 1/200. Considerable difficulty was experienced in obtaining sieves of accurately sized mesh, and the above sizes had to be adopted finally, and the same material was used throughout. In our opinion, it is desirable to have the inert matter of such an approach to uniformity of fineness as will pass through, say 1/80 and be caught by a 1/90. The difference in size between the 1/60 and 1/90 is too large if great accuracy is aimed at, as it is possible for one specimen of the material to consist of a large proportion of 1/60 to 1/70 and a much smaller proportion of 1/80 to 1/90, and a second specimen to have the proportions reversed. In fact, the gradation in size of a 30's difference in mesh is not, in our opinion, sufficiently precise. It is hoped at a later date to repeat the experiments, using particles of inert matter more uniform in size.

A sample of Arley coal was carefully picked so as to be as free as possible from inorganic constituents, and the whole of the sample was ground to pass through a 1/90 mesh sieve. Determinations of the agglutinating value were then made by mixing one unit of coal with increasing proportions of sand (graded 1/60 to 1/90) and adopting the standard American method for the determination of volatile matter in coal (i.e., 1 gram. of coal or mixture is placed in a platinum crucible weighing 20–30 grms., on a silica triangle, over a Bunsen burner, and allowed to remain in the full flame for exactly seven minutes).

The coherence of the coke obtained from the volatile matter test was examined by removing the button and placing upon it a 100-grm. weight, the surface of which was equal to that of the button ob-

* *Comptes rend.*, 1895; see this J., 1896, 186.
† This J., 1913, 397.

tained. When the button crushed to powder under the pressure of the weight the maximum value was considered to have been attained. The term "agglutinating value" is used to describe the proportion of the weight of inert matter to unit weight of coal. With an Arley coal ground to pass through a 1/90 sieve the agglutinating value with sand 1/60 to 1/90 was 15, while with gas carbon 1/60 to 1/90 it was 7.5. It would thus appear that the relative weights of sand and electrode carbon used are directly proportional to the specific gravities of the two substances, and that the 1 grm. of coal requires equal volumes of sand and electrode carbon. It was therefore concluded that the coefficient of agglutination of a coal is a function of the volume or surface of the inert material used. This observation led us to examine the influence of the size of the particles of inert matter upon the agglutinating value of coals, and it was found that with decreasing size of particle the weight of inert material required to destroy the caking power of a coal was diminished. It was therefore decided to examine a number of typical Lancashire seams, and to plot as graphs the results of the agglutinating power determinations. The size of the inert matter experi-

standard American method in this work was to make the results of greater interest, as it enables chemists who do not possess an electric furnace or a standard muffle to compare the results with those we have obtained. At a later date it is proposed to publish the results obtained by carbonising the coal in an electrically heated tube, the temperature of which is controlled by a thermo-couple. The results for the different coals are given in the following table, and the figures are plotted in the diagram:—

No.	Name of coal.	Fineness of electrode carbon.					
		1/180 to 1/200.	1/120 to 1/180.	1/90 to 1/120.	1/60 to 1/90.	1/30 to 1/60.	1/10 to 1/30.
		Weight of electrode carbon per one unit of coal.					
1	Mountain Mine ..	5.0	9.5	14.0	17.0	20.0	24.0
2	Garswood, 9 ft. ..	1.5	2.5	7.0	13.0	22.0	25.0
3	Bacon Mine, tops ..	1.2	2.5	5.0	14.0	19.0	22.0
4	Arley ..	1.2	1.7	4.5	8.0	20.0	25.0
5	Ravine, tops ..	1.0	1.3	3.0	7.0	15.0	19.5
6	Hell Hole, middles ..	1.0	1.1	1.3	7.0	15.0	18.0
7	Chanters, 4 ft. ..	1.0	1.3	1.5	4.5	12.5	21.5

mented with was as previously stated, and in the graphs the size of the particle has been assumed to be the mean between the sieves used, *e.g.*, particles between 1/60 and 1/90 are taken as having an average size of 1/75 mesh.

Average samples of coal were obtained from a number of different seams, each of which was treated in exactly the same manner. The sample was ground till it would pass through a sieve of 1/90 mesh, and the agglutinating value determined. Each experiment was carried out in exactly the same manner, and the reason for the adoption of the

The graph for No. 1, which is practically a straight line, shows no evidence of any bend when the size of the inert matter becomes extremely small. This is interesting in view of the fact that No. 1 coal yields by far the most voluminous and perfect foundry coke of any of those examined.

An examination of the curves leads to one point of importance, namely, that not only does the fundamental property of caking of different coals vary considerably, but the property is influenced by the degree of fineness of the inert substance until, when inert material finer than 1/90 mesh is taken,

the caking property of the coal may be entirely destroyed by less than its own weight of inert matter. Attempts were made to determine the agglutinating value with less than one unit of inert matter, but the results have not, up to the present, led to a satisfactory conclusion, and are not included in this paper. There appears to be no reasonable objection to the conclusion that, if finer inert particles were used than those already experimented upon, the weight of inert material required would be reduced. It is suggested that the most satisfactory manner of determining the agglutinating power of coal is to prepare a graph, showing the relationship between the size of mesh of the inert matter used, and of the weight required to destroy the caking power of a unit weight of coal. This we have called the "agglutination curve"; it will be seen, however, that this determination is rather laborious, and as an alternative we suggest that the agglutinating powers of coal should be measured by the fineness of the inert matter required to destroy its caking properties. The manner of carrying out this test would be to mix one part of coal intimately with, we suggest, three parts of inert material the size of particle of which should be varied, until the coal will no longer yield a coherent button with the inert matter. The caking index would then be expressed in the degree of fineness of the inert matter, *e.g.*, one coal would be, say, 1/200 mesh, the next would be 1/75. It has been found by us that the size of the particle of inert matter does not influence the percentage of volatile organic matter evolved when the coal is heated as shown by the following series of experiments. In these experiments one unit of coal, powdered to pass through a 1/60 sieve and be caught by a 1/90-mesh sieve, was mixed with four units of inert matter (electrode carbon) of the following degrees of fineness and one grm. of the resulting mixture was carbonised under constant conditions:—

Size of inert matter (electrode carbon).	* Percentage of volatile organic matter evolved, calculated on coal taken.
1/10—1/30	28.6
1/30—1/60	29.0
1/60—1/90	29.4
1/100—1/200	29.4
1/200 and finer.	29.6

* Mean of three determinations for each experiment.

It can hardly be hoped to discuss the subject from any but a limited number of aspects in this paper, but the following points may be considered.

It is well known that during the washing of coal a considerable proportion of fine material is produced, part of which contains a high percentage of inorganic matter and fusain. This material has to be disposed of in one form or another, and where the intention is to manufacture coke the fine material or dant is distributed throughout the mass of the coal. It would appear that the addition of this fine dant, which usually possesses a low caking value, and in some cases is entirely without caking properties, although produced from a caking coal, will lead to a distinct difference in the caking value of the coal itself. Further, it is clearly important that the fine material should be mixed throughout the mass of the coal as perfectly as possible, as its accumulation in certain parts of the masses of coal would lead to the production of coke possessing distinct lines of weakness, due to the presence of sufficient finely-divided inert matter to render the coal at this particular point entirely non-caking.

The above observation applies to some extent to the processes in which coal and coke are mixed for use during steam raising, but it would seem that the addition of a small proportion of very finely-divided coke might have a distinctly beneficial

effect in reducing the caking power of a coal which otherwise might be unsuitable for steam raising.

The influence of the inert matter also arises in the stone-dusting of mines; finely-pulverised stone dust is sprayed into mines with a view to eliminate any chance of the fine coal dust in the mine exploding; the mixture of coal and stone dust deposits on the floor, walls, and roofs in the pit. The addition of a small proportion of this very fine material to caking coals would cause the coal to act as a non-caking coal.

It should be mentioned that the figures given in this paper were obtained under conditions which were as uniform as possible and represent the agglutination curves of the coals at one particular temperature. It appears that the shape of the curves may vary considerably with alterations in the temperature, and it is proposed at a later date to prepare curves for certain characteristic seams at a series of constant temperatures.

DISCUSSION.

The CHAIRMAN said that the subject presented many difficulties because of the extraordinary number of variables which had to be reconciled into something approximating to constants, and it was open to doubt whether some of the variables had been entirely eliminated. Had any precautions been taken to avoid prolonged contact of the products of combustion with the walls of the vessel, and to what extent was the vessel packed with the mixture used in determining the curve?

Dr. J. A. WEIL said that in using the so-called "sand" test he had found it necessary to standardise the size of inert material in exactly the same way as described in the paper. Even then the test was rather unsatisfactory, inasmuch as it did not accurately tell how a coal would behave in either a coke oven or a gas producer. The length of time taken in raising the temperature of the mixture of inert material and coal had a very considerable influence upon the strength of the resulting product. This was borne out by experience on a large scale. Coals which were used in coke ovens, heated very slowly under considerable pressure, and without the passage of gas through them, would make a good metallurgical coke; whilst the same coal in moderately small pieces heated moderately slowly in a gas producer, and with a large volume of gas passing through, did not cake to any extent. Owing to the "sand" test being so unreliable, even with the utmost standardisation it was not possible to get any real indication of how the coal would behave in a gas producer. For coke-oven work it was much more easy to guess from the indications given by the sand test, but for gas-producer work it was almost impossible to tell what would happen. It was possible that iron-bearing ash, when heated with an excess of carbon, might yield an ash fusing at a very much lower temperature than would the final fully-oxidised ash of the coal.

Mr. W. THOMSON said that when burning coal in oxygen in the calorimeter nearly all the ash was left in small fused pellets. He supposed that the sand used for mixing with the coal would be taken in its ordinary form, in which case there might be possibly a certain amount of combined water and moisture which might modify the results of the experiments.

Mr. W. H. H. NOMIS suggested that the actual nature of coking might be elucidated by considering the authors' data in the light of simple mathematical reasoning. If coal at the time of coking fused and merely penetrated the natural interspaces between the particles of inert matter, its agglutinating power should be independent of the size of the particles in the test described, because the interspace volume of packed spheres of the same size was independent of their diameter,

viz., 48% for rectangular or "pressure" packing and 26% for normal packing. The latter would only account for values up to 3, and coking would take place with contraction of volume. If, however, coking were considered as a surface effect, the agglutinating power would be reduced as the division or fineness of the inert matter increased, and coking would take place with increase of volume. Both of these were found to be the case. The total surface of the inert matter increased proportionally to the fineness. This was not sufficient to account for the remarkable influence of the size of the inert matter. In one sample, reduction in size from 1/150 to 1/190 mesh should have reduced the binding power of the coal from 4 to 3 instead of from 8 to 1 as found. The explanation for this result might be indicated by the microscope, and connected with the large increase in volume noted. Was it possible that some coals showing high agglutinating values were not suitable for the manufacture of the best metallurgical coke?

Mr. HAILSTONE asked if dried coal had been used in the experiments. The presence of water was liable to affect the texture of the resulting coke.

Mr. GIBSON said that for strict comparison coals containing the same amount of ash should be used, otherwise a variable was introduced which would be difficult to reconcile with the curves shown.

Mr. M. BARASH asked whether the authors could from their experiments advise as to the best standard conditions for obtaining the most representative agglutinating value of a coal. He had carried out satisfactory experiments with the aid of Lessing's apparatus, provided they were undertaken in a certain way. The furnace was heated to the required temperature, switched off for 5 mins., and then the silica tube containing the coal or the mixture of coal and inert matter was introduced, and the furnace switched on again for 7 mins. At the temperature at which the volatile matter was evolved, the walls of the tube were not hot enough to carbonise the tar etc., yet hot enough to allow the volatile matter to escape without deposition on the inside of the tube. The volatile matter came off completely in the first 2 or 3 mins., and then the contents of the tube caked without any possible interference by gases present during the experiment.

Mr. GROUNDS, answering Mr. Norris, said that research had been made with regard to the agglutinating power and the area of the inert matter exposed, and quoted the curves obtained.

Captain SINNATT, in reply, said that the test had been standardised as far as possible, and in order to eliminate the variations mentioned by Mr. Allan the standard American method was used. As a rule the volatile matter was evolved within about 80 seconds. It was probable that the variation in the results of the sand test was due to the size of the sand particles not being the same in each test. Further, it was not necessary for the ferric oxide of the coals to be reduced during the test, as most of the coals examined contained ferrous iron as a constituent of the white partings (ankerite), which were a common feature of Lancashire coals. The presence of iron in the ferrous state would undoubtedly tend to the formation of silicates which might be fusible. Up to the present it had not been possible to standardise the physical appearance and properties of the coke, but it would be considered during the continuation of the work. The fusibility of the ashes in Lancashire coals varied very greatly, and it was for this reason that electrode carbon was adopted as the inert material, in order to eliminate the influence of the combination of sand with inorganic constituents of the coal. With regard to the remarks of Mr. Norris, an attempt had been made to obtain a mathematical expression for the agglutinating value of coal,

and in the case of certain of the coals there appeared to be a distinct law governing the agglutinating value. It was not, however, considered desirable to elaborate these theories until a greater number of coals had been examined. The difficulty of determining the interspace volume was practically insurmountable, as it was not possible to say whether the particles were normally or abnormally piled. In all the experiments coal which had been air-dried for 24 hours was used, and the ash content was that of the ordinary coal. It was most desirable that the conditions under which the test was carried out should be most carefully standardised, and experiments were projected in which it was proposed to use an apparatus of the type described by Lessing.

ESTIMATION OF THE NITRO GROUP IN AROMATIC ORGANIC COMPOUNDS.

T. CALLAN, M.Sc., Ph.D., J. A. RUSSELL HENDERSON, D.Sc., AND N. STRAFFORD.

Of the many methods proposed for the estimation of the nitro group in organic compounds only a limited number are of general application, although many have a limited application to specific nitro compounds. The general methods available for determination of the nitro group may be classified as follows:—

1. Those involving the reduction of the nitro-group to the amino group by use of excess of a reducing agent, followed by determination of this excess with a suitable reagent.

Of these the better known are those involving:—(a) reduction by titanous chloride according to the methods of Knecht and Hibbert collected together in their monograph ("New Reduction Methods in Volumetric Analysis"); (b) reduction by stannous chloride.

2. Those involving the reduction of the nitro group with a reducing agent, followed by determination of the amount of amino compound produced, e.g., by titration, by means of a standard solution of sodium nitrite.

3. Those involving a determination of nitrogen by various modifications of the Kjeldahl method.

The authors have used the titanous chloride method of Knecht and Hibbert very extensively for a large number of substances, in most cases with extremely satisfactory results. It has been found, however, that certain classes of nitro compounds give very low results when analysed by this method, as will be later shown.

The method has one very serious defect when used in the analysis of substances such as are manufactured as intermediate products in the dyestuff industry. The method as recommended by Knecht and Hibbert requires a very small weight of nitro compound to be taken, and when dealing with moist pastes or damp press-cakes the difficulty of weighing out such a small quantity which shall be a representative sample may introduce a serious error. In such cases less convenient and possibly less intrinsically accurate methods may actually give figures more accurately representing the bulk of material.

Although in so many cases titanous chloride gives excellent results, in certain cases, in particular *a*-mononitronaphthalene, *o*-nitroanisole, nitrocresyl methyl ether, and similarly constituted compounds, quite erroneous results were obtained.

Thus a sample of very carefully purified *o*-nitroanisole, b.pt. 162° C. at 12 mm., when analysed by Knecht and Hibbert's method by boiling with excess of titanous chloride in alcoholic solution, followed by back titration of the excess by iron alum, gave NO₂ equivalent to 61.7%, 64.8%, and 64.0% of *o*-nitroanisole. These results, although of the same order, are obviously incorrect. Similarly, with a

sample of pure nitroresyl methyl ether, the method gave figures corresponding to 68.1%, 70.8%, and 71.9% of nitroresyl methyl ether.

In the case of α -mononitronaphthalene the figures were very variable, ranging from 73.8% to 96.1%. In the case of this substance Knecht specifically states* that reduction with titanous chloride must take place in presence of no larger amount of hydrochloric acid than is necessary to keep the titanium chloride in solution. Even on reducing the quantity of acid to this amount we found that it was still impossible to obtain concordant results, and the same was found to be true with α -nitroanisole and α -nitroresyl methyl ether.

It has long been known that during the reduction of certain nitro compounds in presence of hydrochloric acid chlorination may take place simultaneously with reduction.† For complete reduction to a chlorinated amine, however, only two-thirds of the amount of hydrogen is required, compared to reduction to the non-chlorinated amine, since the hydrogen liberated during chlorination is also available for the reduction. Correspondingly, if a chlorinated amine were produced during the reduction by titanous chloride, in the extreme case, i.e., when the product is entirely the chlorinated amine, only two-thirds of the amount of titanous chloride would be required for complete reduction, so that calculating back from this amount analysis of the substance would only indicate 66.6%.

Normally, however, the reduction of a nitro compound to the corresponding amine takes place quantitatively except when conditions favouring chlorination are chosen, e.g., reduction in presence of alcohol. From the results of our analysis of certain substances such as α -nitroanisole, nitroresyl methyl ether, and nitronaphthalene it would appear that reduction with titanous chloride invariably leads to simultaneous production of chlorinated compounds in these cases, and it is in fact possible to isolate such compounds from the products of reduction.

There is therefore a constant danger that analyses of nitro compounds by the titanous chloride method may be quite erroneous unless it is known whether the reduction product is entirely free from chlorinated derivatives. To obviate this source of error—which is very pronounced in the case of α -nitroanisole—the authors have employed titanous sulphate in all those cases where titanous chloride, even in presence of the smallest feasible amount of hydrochloric acid, gave either low or very discordant results, with the result that it has been found that such substances can be smoothly and quantitatively reduced without simultaneous chlorination.

In using titanous sulphate it was at first found extremely difficult to obtain a constant titre of the solution employed against a standard solution of iron alum. This was found to be entirely due to the great ease with which titanous sulphate solution is oxidised at the boiling temperature by atmospheric oxygen—precautions which are sufficient to prevent oxidation of titanous chloride being quite insufficient for titanous sulphate. On boiling titanous sulphate solution in a flask provided with a two-holed stopper with narrow entrance and exit tubes for carbon dioxide, and working with great care to prevent oxidation, then cooling in a stream of carbon dioxide, it remains of constant strength when titrated against a standard solution of iron alum, no special precautions being necessary with the cold solution.

The following table shows results obtained with certain substances which are found to give anomalous results with titanous chloride. In

addition to these substances, many other nitro compounds, the determination of which with titanous chloride gave no difficulty, have been analysed by means of titanous sulphate, concordant results with the two titanous salts being readily obtained.

	Titanous chloride.	Titanous sulphate.
Nitronaphthalene	73.8% .. 89.0% ..	90.9% .. 90.9% ..
α -Nitroanisole *	61.6% .. 61.7% ..	97.6% .. 97.6% ..
"after previous sulphonation	61.0% ..	97.1% ..
Nitroresyl methyl ether* ..	95.6% .. 95.4% ..	96.7% .. 97.0% ..
"after previous sulphonation	68.1% .. 70.8% ..	97.1% .. 96.7% ..
Nitrobenzene	71.7% ..	96.5% ..
"after previous sulphonation	99.2% ..	97.8% .. 98.2% ..†
		99.2% ..

* These substances could only be purified by fractional distillation under reduced pressure and these figures probably represent the actual amount of nitro body present as these results agree exactly with others obtained by the zinc reduction method.

† Low result probably due to volatilisation of the nitrobenzene during the hot reduction.

From these results it becomes apparent that when the Knecht method of titration with titanous chloride is employed for unknown nitro compounds, the analysis should be confirmed by making a duplicate analysis with titanous sulphate, as only by this means can it be assured that chlorination has not simultaneously taken place. It is, however, just as convenient to substitute titanous sulphate for titanous chloride in all cases, and the possibility of this error is thereby avoided.

The use of titanous sulphate also in many cases avoids the necessity of sulphonating, which in some cases, e.g., nitroresyl methyl ether, readily leads to charring, sulphonation being required only in those cases where the nitro compound is sufficiently volatile in steam to entail possible loss during the reduction in boiling solution.

In using titanous sulphate we find that there is no advantage in using a solution weaker than 5%, as this strength has been found to give satisfactory results and avoids the necessity of having to take such small amounts of the nitro compound for analysis. This solution is conveniently prepared by adding 400 c.c. of commercial titanous sulphate solution (about 12%) to about 500 c.c. of dilute sulphuric acid (1 in 10), boiling for a few minutes, cooling, and making up to 1000 c.c. No further addition of acid is necessary.

Reduction with stannous chloride.

Methods for the estimation of the nitro group by reduction with excess of stannous chloride and subsequent determination of the excess of this substance by means of iodine or permanganate date back several years previous to the introduction of titanous chloride by Knecht and Hibbert, the chief modifications of the original method of Limpricht (Ber., 1878, II, 35) being suggested by Young and Swain (J. Amer. Chem. Soc., 1897, 19, 812); Altmann (J. prakt. Chem., 1901, 63, 370); Colver and Prideaux (this J., 1917, 36, 480); Sachs (*ibid.*, 1915), and more recently by Druce (Chem. News, 1919, 118, 133).

The authors have made numerous determinations of nitro compounds, using the various modified methods involving the use of stannous chloride, and in no case have they found the slightest advantage over titanous chloride, whilst in many cases results were less satisfactory; also the time and manipulative skill required and the chances of possible error were considerably greater.

From a study of the papers already referred to it will be seen that chlorinated amino compounds are at least as readily formed during reduction with stannous chloride as with titanous chloride, and the objections raised to the use of the latter apply to the former with equal force.

* "New Reduction Methods in Volumetric Analysis" 1914 Ed., p. 130.

† Fittig, Ber., 1875, 8, 15. Schöler, Ber., 1878, 11, 1201. Gabriel and Stelzner, Ber., 1896, 29, 306. Blankens, Rec. Trav. Chim., 1907, 25, 365. Ramberger, Ber., 1895, 28, 251. Hurst and Thorpe, Chem. Soc. Trans., 1915, 107, 941.

The authors of papers describing the use of stannous chloride as a reducing agent all state that they get results lower than theoretical in many cases. They incorrectly assume that stannous chloride is not a sufficiently energetic reducing agent, having failed to appreciate the fact that simultaneous chlorination and reduction may take place.

Reduction of the nitro group to the amino group and subsequent determination of the latter.

We have been unable to find any direct references in the literature to this method, which, although only of limited application, is yet of very great value in the case of a considerable number of nitro compounds, i.e., those which can be smoothly reduced to an amino compound which can be quantitatively converted into a diazo compound by means of nitrous acid. About 1/20 grm.-mol. of the nitro compound is either dissolved or suspended in excess of dilute hydrochloric acid and zinc dust gradually added in considerable excess, the reaction being kept vigorous by occasionally warming the solution. After about an hour the solution is filtered, diluted, cooled by addition of ice and titrated with $N/2$ sodium nitrite until a drop of the solution applied to starch-iodide paper used as an external indicator shows excess of nitrous acid to be present.

In this method it is immaterial whether chlorinated amines are formed or not, provided such chlorinated amines, as is usually the case, react with nitrous acid to form diazo compounds. As will be seen, 2000 c.c. of $N/2$ sodium nitrite is required for each grm.-mol. of mononitro-compound reduced to monoamino-compound.

We have found the method extremely useful for a considerable number of substances, e.g., nitroanisole, *p*-nitrochlorobenzene-*o*-sulphonic acid, *p*-nitrotoluenesulphonic acid, etc., and in all cases have obtained excellent agreement with determinations made with titanous sulphate, though not necessarily with titanous chloride. Thus, a sample of nitroanisole gave figures of 97%, 97.6%, and 64.0% when analysed by these three methods respectively. The method has the decided advantage in works' practice that it is free from manipulative difficulties and involves no special form of apparatus, whilst the fact that a comparatively large weight of sample can be taken for analysis means considerably less chance of error due to sampling difficulties.

It is important to insure that both the acid and the zinc dust are free from iron or, alternatively, to make a blank determination to ascertain what amount of standard nitrite solution is taken up by traces of ferrous iron present after reduction.

It is not proposed here to discuss the value of the Kjeldahl method, with its voluminous literature, for the determination of the nitro group, as although the authors have carried out a considerable amount of work on the subject, particularly from the novel point of view of the use of titanous sulphate as both reducing and catalytic agent for the promotion of oxidation, the results are at present not sufficiently advanced to permit of publication.

In conclusion, we desire to express our thanks to The British Dyestuffs Corporation (Blackley), Limited, in whose Central Analytical Laboratory the work was done, for permission to publish the results of this investigation.

DISCUSSION.

Prof. KNECHT said that the fact that the titanous chloride method as originally recommended by him had failed in the case of α -nitronaphthalene, had been communicated to him some years ago. It had been found that by using very much weaker hydrochloric acid apparently reliable results could be obtained. There were several peculiarities in the

reaction of titanium salts which it seemed difficult to explain. For example, when diazobenzene chloride was treated with titanous chloride in concentrated hydrochloric acid solution there was no reduction, whereas in a very dilute solution, in the presence of a small amount of hydrochloric acid, the action was quantitative. Again, when a dilute solution of titanous chloride was boiled with sodium persulphate very little action took place, but if a 15% solution of sulphate were used the reduction was quantitative. Titanous fluoride used in place of the sulphate might give equally reliable results while at the same time being more stable in contact with air. Was the *o*-nitroanisole sulphonated in carrying out the determination or was the product dissolved in alcohol? Alcohol was always liable to introduce certain irregularities into the process, and, personally, he thought that sulphuric acid would, in the majority of cases, even if it only acted as a mechanical solvent, give better results.

Prof. A. LAPWORTH said that in the application of stannous chloride some substances gave results 10% too low, even though they were sulphonated nitro compounds. In such cases it was desirable to standardise the stannous chloride solution with a nitro compound which was nearest to that which was to be estimated. Orton and Jones had shown that the aceto-chloroanilides and hydrochloric acid first reacted to form acetanilides and free chlorine, which then reacted to give the chlorinated acetanilides. If Orton's explanation was general then there was a possibility of effecting a great variation in the results according to the manner of titration.

Mr. L. G. RADCLIFFE said that after some difficulty he had applied titanous chloride to the determination of the nitro musks in admixture with acetanilide.

Dr. CALLAN, in reply, said that they had made practically no differences in the technique of the original method as devised by Prof. Knecht. He did not agree with Prof. Knecht that it was generally advisable to sulphonate. This involved the use of oleum sometimes for some hours, which in many cases, for example, *o*-nitrocresyl methyl ether, caused charring, whilst by dissolving in alcohol and adding to the titanous sulphate solution the analysis required only about 10 minutes. Solution in alcohol certainly increased the likelihood of chlorination, and therefore when using titanous chloride sulphonation was decidedly advantageous, but with titanous sulphate where no chlorination was possible an alcoholic solution was greatly to be preferred. Attempts to use stannous sulphate in place of stannous chloride gave unpromising results, this material being very difficult to work with.

Newcastle Section.

Meeting held at Armstrong College, Newcastle, on November 19, 1919.

PROF. P. P. BEDSON IN THE CHAIR.

A STUDY OF THE FRUIT OF SCHLEICHERA TRIJUGA, WITH SPECIAL REFERENCE TO THE GENERATION OF HYDROCYANIC ACID IN THE SEED.

BY NAGENDRA N. SEN-GUPTA, B.Sc.

Schleichera trijuga is a large deciduous Indian tree belonging to the natural order Sapindaceae. It is of very common occurrence in dry forests all over India—Bengal and Assam being possibly excepted—

and also in Ceylon and the East Indian Archipelago. In virtue of the quality of its timber it is a factor of considerable importance in the forest economy of India, but this study is concerned with the fruit of the tree, the full recognition of the value of which as a source of vegetable fat and cattle food is almost sure to raise its silvicultural status.

The annual production of fruits is enormous, although it is very doubtful whether any serious efforts have so far been made to collect them systematically and to dispose of them in such a way as to obtain the best value of the fat as well as of the residue left after expression.

The cyanogenetic character of the seed of *Schleichera trijuga* was revealed more than a quarter of a century ago in connection with certain investigations into the properties of "Macassar oil," but, as far as I am aware, very little work has been done on the subject. But for the outbreak of the war in 1914 the subject would have been studied before now at the Imperial Institute, through whose generosity the material, which formed the basis of my work, was made available to me.

The work embodied in this paper falls under the following three heads: (1) A general survey of the constituents of the various parts of the fruit from the feeding point of view; (2) A study of the cyanogenesis in the seed; (3) An examination of the fat.

The constituents of the various parts of the fruit.

The fruit is a nut varying considerably in shape and size. The commonest and perhaps the typical shape is ovoid, the diametrical range being from $\frac{1}{2}$ in. to $\frac{3}{4}$ in. Generally the fruit is one-seeded, but twinning is by no means uncommon. The seed is protected by two distinct shells, separated by an intervening dark-brown layer of soft membranous character. Starting from the exterior, these four morphological units may be represented as follows: Outer shell, 50.8% by weight; membranous layer, 12.4%; inner shell, 14.6%; seed, 22.2%. Analysis of the two shells and the membranous layer shows that their inclusion in the composition of any kind of feeding-stuff is entirely out of the question. The shells might, however, be profitably treated for the manufacture of charcoal and volatile products.

The most obvious features of the seeds are their excessively high fat content and their extraordinary liability to the attack of fungi. About 70 per cent. of the fruits placed at my disposal were affected by one or more species of fungi, although the damage to the seed was not a constant consequence. The fact that the sphere of fungoid activity is inside the fruit, with the outer shell intact, indicates that the fungi may be of Indian origin and not the result of inoculation during storage at the Imperial Institute. Fully 40 per cent. of the fruits examined had their interior absolutely destroyed. Another 25 per cent. showed seeds in an advanced stage of disintegration; these chemically altered seeds will be referred to as "diseased seeds," in contradistinction to healthy ones.

The ether-extract from diseased seeds shows a very high degree of decomposition of the fat, the acid value being 109.6 as compared with 13.06 for healthy seeds.

The following figures for the composition of the two kinds of seeds have been obtained by the conventional method of representing the percentage of soluble carbohydrates by the figure obtained by subtracting the combined percentages of water, oil, proteins, fibre, and ash from 100. It is realised that, owing to the fact that nitrogen is present in the seed in at least three forms—true proteins, amides etc., and glucoside—the use of the figure $N \times 6.25$ will give an erroneous idea of the protein and also therefore of the carbohydrates, but since the identity of the glucoside has not been definitely established, it is proposed to adhere to the standard method.

	Healthy seed.	Diseased seed.
Moisture	3.20	3.00
Oil	67.13	63.23
Proteins	18.20	13.30
Carbohydrates	6.14	11.39
Fibre	3.40	5.63
Ash	1.93	2.85
Total nitrogen	2.912	2.128
N as true proteins	2.436	
N as amides etc.	0.448	

The amount of hydrocyanic acid yielded by healthy seeds under the most favourable conditions of hydrolysis hitherto observed has been 0.574%, corresponding to 0.298% of nitrogen. The discrepancy between this figure and the difference between the percentage of total nitrogen and the combined percentages of nitrogen as true proteins (precipitated by copper hydroxide) and amides etc. appears only to be capable of explanation by assuming that copper hydroxide not only prevents the hydrolysis of the glucoside by the water used, but also precipitates the glucoside together with the true proteins. This point remains to be definitely settled. The cyanogenetic hydrolysis of the glucoside during digestion with concentrated sulphuric acid is not a possibility, since when pure amygdalin is digested in a similar way the entire nitrogen-content is recovered as ammonium sulphate.

Probable composition of the feeding stuff derived from healthy seed.

The possible or advisable degree of expression of the seeds can only be definitely established by actual experiments on the manufacturing scale. The inhibitory effect of the common fat-solvents on the action of the enzyme (discussed later) indicates the superiority of the extraction method over that of expression in dealing with the fat in this particular case, unless it is possible to destroy the enzyme by heat (wet or dry) prior to expression without affecting the fat. In the absence of such heat-treatment the expression method will be fraught with the danger of contaminating the fat with hydrocyanic acid and leaving a large proportion of the glucoside together with the active enzyme in the residue, as it has been observed that a certain amount of hydrolysis takes place in crushing the material even in the absence of external moisture. As it is practicable to remove the last trace of fat from the seed by the extraction method, a composition may be suggested for the residual cattle food which will be a fair approximation to what should be the case in actual practice. In view of the striking poverty of carbohydrates in the seed, the fat-content of the residual food must be higher than is the case in the ordinary cattle cakes and meals. Taking all the facts into consideration, it appears that the percentage of fat in the residue should not be less than 15. Calculating on this basis, it is found that if 91.4% of the fat present in the healthy seed is removed, the composition of the residue should include 15 per cent. of fat. Thus, 100 lb. of seed should yield 38.67 lb. of cattle food containing moisture 8.28, oil 14.99, protein 47.07, carbohydrates 15.88, fibre 8.79, ash 4.99 per cent.

A study of the cyanogenesis in the seed.

The literature on the subject is so obscure that it is difficult to say with certainty when and by whom the discovery of the cyanogenetic property of the seed was made, but it is more than probable that the credit belongs to Trümmel,* who, working alone in 1889, and in conjunction with Kwassick,† in 1891, was able to obtain hydrocyanic acid both from the seed and the fat. The fat has since been examined by several workers, most of whom have confirmed the presence of hydrocyanic acid in it.

It is hardly conceivable that hydrocyanic acid can be present in the seed in a pre-formed state, and it

* Apoth. Zeit. 1889.

† Pharm. Zeit. 1891.

may be assumed that its source is a cyanogenetic glucoside. The hydrolysis under different conditions is quite typical of enzyme activity, hydrocyanic acid and a reducing sugar having been detected. Attempts to isolate the glucoside have proved unsuccessful.

The usual method of isolating enzymes has led to the separation of a nitrogenous substance which, when dry, presents the typical appearance of an enzyme, and which has therefore been taken to be the agent responsible for the hydrolysis of the glucoside. The dry white powder resulting from the gelatinous mass precipitated by an excess of alcohol is insoluble in water, but forms an opalescent suspension. Such enzymic solutions will not hydrolyse pure amygdalin or the glucoside in the crushed seed in which the enzyme had previously been destroyed. Further, 1 grm. of ground seed, which, under the same conditions of temperature etc., yielded over 3 mgrms. of hydrocyanic acid in a medium of pure water, was incapable of evolving even a trace of the acid when the hydrolysis-medium consisted of alcohol and water in the same proportions as used for the precipitation of the enzyme. In this respect the enzyme resembles urease.*

Evolution of hydrocyanic acid under different conditions of hydrolysis.

A number of experiments have been carried out with the apparatus devised by Mr. S. H. Collins for his research on linseed.† My best thanks are due to him for permission to use his apparatus. The material is hydrolysed at constant temperature and the hydrocyanic acid evolved is removed by an adjustable current of hydrogen and fixed as sodium cyanide, which is estimated colorimetrically. The hydrocyanic acid has also been estimated volumetrically by means of $N/20$ silver nitrate solution, the end-point being quite sharply defined. The volumetric method has always given somewhat higher results than the colorimetric method, but the latter is a reliable guide to comparing the effects of various conditions on the hydrolytic action of the enzyme.

The results of these tests have proved that cyanogenesis is confined to the seed. The evolution of hydrocyanic acid from diseased seeds is very small. At 25° C. 1 grm. of ground diseased seed evolved only 4% of the amount obtained under similar conditions from healthy seeds, but at 35° C. the amount increased to 19%. The reason for this increase is not apparent, since the enzyme activity is at a maximum at about 25° C. (see later). The figures showing the rate and amount of evolution of hydrocyanic acid in the two cases both at 25° and 35° C. are tabulated below:—

Table I.

Weight of material used=1 grm.

Time.	Mgm. HCN from healthy seed at 25° C.	Mgm. HCN from diseased seed at 25° C.	Mgm. HCN from healthy seed at 35° C.	Mgm. HCN from diseased seed at 35° C.

‡ Collins—Rate of evolution of HCN from linseed under digestive conditions. Proc. of University of Durham Phil. Soc., Vol. IV., Part 3. Compton—Constancy of the optimum temperature of an enzyme under varying concentrations of substrate and of enzymes, Roy. Soc. Proc., B, Vol. 28, 1914.

activity have found that the optimum temperature for enzymes lies somewhere about 45° C. My experiments with the enzyme of *Schleicheria* seeds indicate that in this case the optimum is 25° C., at which temperature the yield of hydrocyanic acid is, roughly, 120% higher than that at 35°, while at 15° the evolution is less than at 25°, but is still in excess of the amount given off at 35° C. Readings have also been taken at 45°, 65°, 75°, and 95° C., and the results show a progressively inhibitory effect of wet heat.

The following results of volumetric estimations made at 15°, 25°, and 35° C. give an idea of the total amount of hydrocyanic acid evolved. These results confirm the statement made as to the optimum temperature of enzyme activity: At 15° C. 2.499 mgrms. of HCN was evolved per grm. of material; at 25° C., 3.982 mgrms.; at 35° C., 1.890 mgrms.

To observe the effect of steam 3 grms. of the ground material was subjected to a current of steam for half an hour, the distillate being collected in a dilute solution of sodium hydroxide. The steamed material was examined for hydrocyanic acid in the usual way for about four hours at 25° C. The distillate showed the presence of 0.54 mgrm. of HCN (0.18 mgrm. per grm. of material), while the steam-treated material failed to show any trace of the acid. The effect of steam on the whole seed was the same as with the ground material. Steam treatment may thus prove a suitable way of dealing with the enzyme if condensation on a large scale in contact with the material can be avoided.

The power of the enzyme to resist the effect of dry heat is very considerable indeed. Whilst half an hour's steaming is practically fatal to the enzyme, the ground material dried for half an hour at 100° C. evolved in contact with water at 35° C. 1.5 mgrms. of hydrocyanic acid per grm. of the material as compared with 1.62 mgrms. normally. Similar treatment for longer periods showed that dry heat, though slow in its action, eventually destroys the enzyme (see Table II.).

In deciding on the most convenient method of destroying the enzyme on the manufacturing scale the claims of dry heat should be considered on account of its simplicity and practicability. The process is already adopted in connection with the manufacture of linseed cake.

* Crushed before examination for HCN.

Enzymic response to acidity.

The behaviour of the enzyme in the presence of acid is somewhat remarkable. Whilst $N/1000$ hydrochloric acid at 35° C. liberated practically as much hydrocyanic acid as water, the use of $N/500$ acid resulted in the evolution of at least 73% more hydrocyanic acid than with water at the same temperature. At 25° C. volumetric estimation indicated that 5.74 mgrms. of hydrocyanic acid was liberated from 1 grm. of material, as compared with 3.982 mgrms. when water was the medium of hydrolysis. It thus appears that a certain degree of acidity, probably depending on the normal extent of ionic

dissociation of the acid, is stimulative to the activity of the enzyme. In this connection it may be noted that H. E. Armstrong* found that carbonic acid up to a certain point had an accelerative influence on the activity of urease, which he attributes to the function of the acid neutralising the basic product of hydrolysis (ammonia) which would otherwise tend to combine with the carboxyl of the "agent" radical of the enzyme and thus destroy its power of hydrolysis. This explanation is not applicable to the present case. I am inclined to think that the concentration of hydrogen ions is the factor which governs the behaviour of the enzyme in this series of experiments. The very slight ionic dissociation which characterises water in the normal state does not perhaps supply the concentration of hydrogen ions needed for the maximum activity of the enzyme possible under the other experimental conditions, such as temperature etc. The optimum hydrogen-ion concentration for the enzyme of *Schleichera* seeds is supplied by $N/500$ hydrochloric acid, or thereabouts.

Effect of fat solvents on the enzyme.

The ground material was treated with anhydrous solvents and the extracted material examined in the usual way at 35° and at 25° C. In all cases the evolution of hydrocyanic acid was either nil or so low as to be almost negligible. 3 grms. of material percolated with ether for three hours, when examined at 35° C. evolved no acid in one case and only 0.16 mgrm. in another. In another experiment conducted at 25° C. with the same quantity of material after four hours' ether extraction, 0.29 mgrm. of acid was evolved. Extracted material after exposure to the atmosphere for 12 days failed to evolve any acid. Experiments have indicated that it is the enzyme and not the glucoside that suffers from the action of ether. Petroleum spirit has a similar inhibitory power. The solvent used had a very low b. pt., and it is probable that the vapour of commercial petroleum spirit would be even more inhibitory. In one experiment 2 grms. of material extracted with petroleum spirit for 2½ hours failed to give off any hydrocyanic acid, and in another 3 grms. of material extracted for three hours evolved 0.57 mgrm. (temperature 25° C.). Carbon bisulphide and carbon tetrachloride have a similar effect on the enzyme.

The above observations indicate that by the use of any of the common fat solvents and by allowing the solvent to act on the enzyme for a sufficiently long time, the safety of the residue as a cattle food can be practically guaranteed, provided, of course, no other food taken simultaneously contains an enzyme capable of hydrolysing the glucoside. The cyanogenetic hydrolysis of the glucoside by enzymes secreted in the animal body is highly improbable. Pure amygdalin fed to animals has been found to be without any deleterious effect.

Other antiseptics, including phenol, salicylic acid, hydrogen peroxide, mercuric chloride, and bleaching powder, are all more or less effective in inhibiting the action of the enzyme. Mercuric chloride is the most effective.

A few experiments have been carried out to determine the influence of a number of commonly employed cattle foods, such as grass, hay, roots, and dried silage. A temperature of 39° C. was maintained throughout these experiments. The proportions of the ground seed and of the food were determined with reference to rations in vogue. The evolution of hydrocyanic acid was greatest in presence of silage and least with grass. Silage increased the activity of the enzyme by more than 100% and hay by 33%. In presence of roots the evolution is slightly higher than normally, whilst grass depresses the activity by about 30%. The increased action

with silage and with hay is the result of the acidity of the material.

Estimation of a reducing sugar due to hydrolysis of the glucoside.

The seed is remarkably deficient in reducing sugars, but the water in which the hydrolysis was carried out contained an appreciable amount of a reducing sugar (probably dextrose). Experiments indicated an approximate ratio of 1 HCN:3½ dextrose, showing that the principal glucoside has a high nitrogen content.

The enzyme.

The precipitated enzyme material, dried and dissolved in water, was without activity towards either amygdalin or the glucoside in the seed in which the enzyme had previously been destroyed. The aqueous extract of the seed, without alcohol, is capable of hydrolysing both. The activity of the aqueous extract was vigorous during the first two days, after which it began to decrease and became nil in the course of a week. The fact that amygdalin was decomposed by the enzyme of the seed indicates the presence of an emulsin-like body. Although it has not been possible to discover directly any other products of hydrolysis than hydrocyanic acid and dextrose, it should be mentioned that a faint, but unmistakable, smell of benzaldehyde was developed in the seed when a fairly large quantity of it was submitted to very high pressure, but as the quantity produced is very small it is probable that there are at least two glucosides in the seed, and that the glucoside responsible for benzaldehyde is present in a very small proportion.

Examination of the fat.

Schleichera fat has already been examined by Wijs, Itallie, Glenk, Lewkowitsch, and others. The fat is known by several names, e.g., Kon oil, Kusum oil, Macassar oil, etc.; it has only attained commercial importance for the manufacture of hair oil.

The freshly extracted material is a solid, which begins to liquefy at a comparatively low temperature. It possesses a pleasant smell and is yellowish-white in colour, which changes into dark brown on prolonged heating accompanied by a marked change of odour. The following results were obtained:—Sp. gr. $99^{\circ}/15^{\circ}$ C., 0.86. M. pt., initial 21° C., complete transparency 31° C. Solidifying pt., 29° — 18° C. Saponification value: healthy seeds (a) 229.1, (b) 214.4; mixture of healthy and diseased seeds, 207.6. Iodine values 52.1, 55, 54.6 respectively. Refractive index, at 21° C., 1.46757; at 27° , 1.46655; at 31.5° , 1.4646; at 45° C., 1.4636. Acid value: fat from healthy seeds 13.06; after storing three months 16.28; fat from diseased seeds 109.6.

My best thanks are due to the Director of the Imperial Institute, and to Dr. T. A. Henry, for their kindness in supplying me with the material of the research, and to Mr. S. H. Collins, of the Agricultural Department, of Armstrong College, who has given me the benefit of his experience and allowed me to use his apparatus.

Communications.

A PRELIMINARY ACCOUNT OF THE CHEMISTRY OF THE NILE SUDD.

BY A. F. JOSEPH, D.S.C., F.I.C., AND F. J. MARTIN, M.A.

One of the chief obstacles to navigation in the upper reaches of the Nile and its tributaries is the blockage caused by masses of vegetable matter, locally termed "sudd," an Arabic word meaning blockage or dam. This is composed of fixed and

* Roy. Soc. Proc, 1913., B, 86, 328.

swimming plants, which vary from place to place. Of the many species that have been identified the most important are a papyrus (*Cyperus papyrus*), which grows to a considerable height, often exceeding 15 ft.; a grass (*Panicum pyramidale*), known locally as "Um Soof," a name meaning "Mother of Wool," given on account of the peculiar hairy character of its leaf sheath; and a convolvulus (*Ipomoea aquatica*). "Um Soof" has recently been the subject of an investigation on account of a dermatitis caused when its fine hairs come in contact with the skin, and which appeared to be produced mechanically and not by an actively irritant constituent.

As stated above, the sudd is a great impediment to river transport. From the Zeraf mouth, 525 miles above Khartoum, to Shambe, a distance of 300 miles, a passage through the main channel is at times only kept clear with difficulty, whilst all the tributaries in this region are blocked for many miles.

The vast area of the sudd is, of course, only known very roughly; experienced observers, however, estimate the denser portion at not less than 5000 square miles—150 miles long and 30–40 miles wide—in extent. It is obviously of the greatest importance to consider the possibility of utilising such a gigantic store of material.

Possible utilisation of Sudd material.

Various proposals have been made in recent years to utilise the material of the sudd as fuel. The amount available for this purpose has been estimated at 45 tons of air-dried papyrus per acre, from experiments carried out on the spot some years ago. Thus there is a store of 144 million tons in the area under consideration.

The calorific value of dried papyrus has been found to be about 2000 calories per gm., against 8500 for bituminous coal; the 144 million tons may therefore be put thermally equivalent to 28 million tons of coal.

In terms of energy the 144 million tons should, if burnt, be capable of furnishing 3·6 million horse-power continually, on the assumption that 10 lb. of the material is required for the generation of one horse-power hour against 1½ to 2 lb. of coal. This amount of power is about three-fourths of the theoretical average power of the Niagara Falls, and is an enormous asset.

Fuel is only one of many ways which have been suggested for the use of the sudd material; others, such as paper pulp, rope fibre, fertiliser (from the ash), and distillation products are amongst the possibilities of the future, and a detailed chemical examination of the subject is obviously desirable.

References.

Very few references to the sudd are to be found in chemical literature. Cross and Bevan ("Paper Making," p. 161) refer to papyrus as a possible source of material for fine papers of the esparto type, and an experimental treatment of the same subject by the late Dr. W. Beam forms the subject of Bulletin No. 2, 1915 (Chemical Section) of the Wellcome Tropical Research Laboratories (see this J., 1915, 792). Cresswell (this J., 1915, 389) refers to the sudd as a possible source of potash, and it will be seen that this is fully borne out from the analysis recorded below.

Proximate analysis.

Two samples of papyrus were examined, the first (a) collected some years ago, and therefore subjected to a long period of air drying, and the second (b) in September, 1919, the analysis being carried out in October. The Um Soof was obtained about the same time as (b). Arrangements are being made to obtain other samples collected at

different times of the year, as seasonal variations in the amount and composition of the ash may occur (compare Purvis, Proc. Camb. Phil. Soc., 19, 261; also Chemical Abstracts, 1918, p. 1737).

The analysis was confined to the determination of groups of compounds rather than of individuals (compare Dore, J. Ind. Eng. Chem., 1919, 11, 536). The following were the determinations made:—(a) *Moisture*, determined by heating in the steam oven at about 97°C. for four hours. (b) *Mineral constituents*.—Ash was determined by ignition in a platinum basin over a spirit Bunsen burner for about two hours. The volatility of potassium chloride under these conditions is unfortunately sufficiently great to render the results somewhat uncertain. (c) *Fatty and waxy matter*.—The dried material was extracted for about 10 hours in a Soxhlet extractor with a mixture of alcohol and benzene in equal proportions. (d) *Soluble proteins*.—The dried material was treated with water at room temperature for 24 hours, the mixture filtered, and the filtrate evaporated to dryness on a water bath (soluble protein = N in residue × 6·25). (e) *Insoluble protein* was determined by subtracting (d) from the total protein. (f) *Pentosans*.—The dried material was boiled with 12% hydrochloric acid in a flask connected with a condenser, and the furfural estimated in the distillate by means of phloroglucinol in the usual way. (g) *Soluble carbohydrates*.—The water-soluble portion was assumed to consist of protein, carbohydrates, and mineral matter. The first and last of these being determined, the amount of the soluble carbohydrates was obtained by difference. (h) *Fibre*.—The material was boiled with 1·25% sulphuric acid for half an hour, the mixture filtered and washed, and the residue boiled with 1·25% caustic soda for half an hour. The undissolved material dried at 110° C. was weighed, ignited, and the weight of the ash subtracted from the weight of the residue dried at 110°, was taken as fibre.

Methods (f) and (h) are those of the Association of Official Agricultural Chemists (U.S. Dept. of Agriculture, Bureau of Chemistry, Bul. 107).

Stems of papyrus and Um Soof were used for the proximate analysis. The former consists of long, straight rods of triangular section varying from ½ in. to 1½ in. along the edge. It is exceedingly light, the apparent specific gravity of pieces cut from different stems being 0·174 (mean of six determinations). When reduced to pieces about 1 c.c. in size the "bulk density" of the uncompressed material is only 0·1, i.e., about 300 cub. ft. to the ton.

The analytical results obtained were as follows:—

	Papyrus stems	Um Soof stems
(a) Moisture	5·5	5·0
(b) Mineral constituents	6·0	8·6
(c) Fatty and waxy matter	9·4	5·2
(d) Soluble proteins	0·8	3·6
(e) Insoluble proteins	0·8	1·1
(f) Pentosans	24·2	28·2
(g) Soluble carbohydrates	7·9	6·6
(h) Fibre	40·4	38·8
Total	95·0	97·1

Dore (*loc. cit.*) found a similar deficiency to that shown above in his analysis of five different kinds of American wood. This may be due to neutral volatile substances which are lost during hydrolytic changes.

The mineral matter is dealt with in detail below. The total protein figures are between those for woods and grasses; the papyrus, being more of a ligneous nature than Um Soof, contains, as would be expected, the smaller proportion.

The figures for fibre may be of practical importance if the material is to be used for paper pulp manufacture. In Dr. Beam's experiments on this

subject, previously referred to, it was found that erude pulp or "half stuff" was readily obtained by heating papyrus stems (either green or dry) under pressure to about 150° C. for a few hours with water alone, no caustic soda or other chemicals being required. As Beam pointed out, the advantage of such a method would be very great in a region so far removed from chemical supplies and where recovery of waste products would be an additional difficulty. Beam found that the air-dried papyrus yielded about 40% of dry "half stuff" and about 20% of dry bleached pulp; the former figure is in close agreement with the value for "fibre" recorded by us.

Mineral constituents.

The following are the most important of the determinations made:—

Composition of the entire ash.

Percentage.	Papyrus A Flower head	Papyrus A stems	Papyrus B stems	Um Soof stems
Total ash from air-dried material.	11.6	4.66	6.00	8.56
Calculated on the ash				
K ₂ O ..	10.50	34.50	35.27	29.62
Na ₂ O ..	0.52	N.D.*	8.07	1.90
CaO—MgO ..	3.54	N.D.	3.12	4.85
Fe ₂ O ₃ —MnO ..	3.04	3.80	1.44	1.71
SiO ₂ ..	59.01	36.36	32.58	50.84
CO ₂ ..	1.42	N.D.*	4.27	—
Cl ..	1.70	10.43	16.60	12.05
SO ₂ ..	Trace	Trace	Trace	Trace
P ₂ O ₅ ..	5.04	3.92	2.35	3.64
C ..	9.55	—	—	—
Deduct oxygen equivalent to chlorine	0.39	2.35	3.72	2.72
Total ..	99.93	—	99.98	101.89

*Not determined.

The most important of the above results is the high potash content of the stems; at the same time the amount of chlorine indicates that a considerable proportion is soluble in water. The following table gives the complete analysis of the water-soluble portion of papyrus stems, sample B:—

The water-soluble portion had the following composition (calculated on the total ash): Total water-soluble salts 57.20%, K₂O 29.72, Na₂O 5.59, SiO₂ 8.00, CO₂ 3.78, Cl 11.76%; total, 61.85; deduct oxygen equivalent to chlorine 3.32% = 58.53%. The following composition for the water-soluble portion would agree with the above figures: NaCl 10.53, KCl 17.61, K₂CO₃ 11.88, K₂SiO₃ 17.27%; total, 57.29%. Such a product containing 39% of potassium (or over 50% as K₂O) might well be the basis of a very valuable fertiliser, and it is hoped to carry out some field experiments to test this next season. At the same time the whole ash (containing 35% K₂O) will be examined for manurial value.

Action of water.

The action of water on dried papyrus has been examined at ordinary and elevated temperatures and pressures.

In the first series of experiments the air-dried material was treated with cold water (about 30° C.) for 24 hours, the filtered solution evaporated to dryness, and the extract dried in the steam oven.

The following results were obtained:—

Percentages calculated on the original material.			
	Papyrus B		Um Soof
	%	%	%
Dried extract	9.0	12.0
Mineral matter	2.6	2.0
Ignition	2.3	—
soluble in water after

A 20-grm. portion of the material was heated in the water bath with 500 c.c. of water, and the filtered extract evaporated to dryness. The undissolved material was heated in the autoclave with water for four hours at four atmospheres pressure

(150° C.), and the total extract and the mineral matter again determined.

In one experiment an attempt was made to retain the volatile products of hydrolysis from the autoclave. A small amount of carbon dioxide was evolved. The distillate was titrated against standard alkali and the results expressed in terms of acetic acid. The extract in the autoclave was also examined for acid.

The results given below are for the extraction by hot water at ordinary pressure, followed by four hours in the autoclave. All the results are percentages calculated on the original material.

The figures show that water extracts about one quarter of the material, including about four-fifths of the mineral constituents. Samples A and B gave substantially the same results.

In neither experiment is 100% of the material accounted for, the deficiencies being 16.3 and 7.6% respectively.

	Dried extract		Mineral matter		Mineral matter soluble in water after ignition	
	A %	B %	A %	B %	A %	B %
On the water-bath ..	9.66	9.39	3.21	3.82	2.75	3.25
Further material extracted in the autoclave ..	13.79	16.56	1.52	1.56	0.68	0.63
Total extracts ..	23.65	26.95	4.73	5.58	3.43	3.83
Residue in the autoclave ..	60.00	65.5	1.50	0.79	0.22	0.11
Total mineral matter extracted ..	—	—	6.23	6.35	3.65	3.99

An additional experiment was carried out in which 20 grms. of sample B was heated in the autoclave with water under a pressure of about four atmospheres, the valve being connected to an absorption apparatus. After two hours the heating was interrupted, the contents of the autoclave filtered, and determinations made of the acidity of the extract and of the distillate, and the weight, protein content, and ash of the extract. The residue left after filtration was then returned to the autoclave and the heating with water continued for another two hours, after which the same determinations were made. After a third heating with water, followed by the same analytical determinations, the residue was dried at 100° C., weighed, and the protein and ash determined in it. The collected results, expressed as percentages on the original material, are given below:—

Percentage	First 2 hours.	Second 2 hours.	Third 2 hours.	Total
Volatile matter absorbed in the tube ..	0.185	0.100	0.145	0.33
Acid in distillate as acetic acid ..	0.245	0.220	0.060	0.52
Acid in extract ..	0.765	0.810	0.415	1.99
Protein in extract ..	0.61	0.42	0.18	1.21
Mineral matter in extract ..	4.01	1.11	0.43	5.55
Soluble carbohydrate in extract ..	11.93	10.34	2.68	24.95
Total material removed ..	17.74	13.00	4.53	35.27

The weight of the residue (11.3 grms.) was 56.5% of the original material taken; 35.3% is accounted for as above, so that there is 8.2% not identified. The residue contained 0.81% of protein and 0.07% of mineral matter calculated on the original material; the autoclave treatment therefore removed rather more than half the former and practically the whole of the latter, in three successive heatings. The first four hours extracted four-fifths of the total material dissolved.

Conclusions.

(a) Examination of papyrus and Um Soof—two of the most important constituents of the Nile sudd indicates that these two plants may be of economic importance in paper pulp manufacture and as a source of potash.

(b) The ash of papyrus stems contains more potash than that of Um Soof, but this is more than

balanced by the higher proportion of ash yielded by Um Soof. Calculated on the dry plant, papyrus stems contain 21 and Um Soof stems 23% of potassium oxide.

(c) Papyrus stems are readily acted on by hot water, more especially under a pressure of about four atmospheres. Treated in this way, practically all the mineral matter and most of the protein passes into solution, and the residue constitutes a satisfactory "half stuff" for paper.

It is hoped that the work will be continued in order to complete the above preliminary account of the chemistry of this important material.

Our best thanks are due to Mr. F. J. Tear, of the Sudan Forests Department, who kindly supplied the samples of material, and to Mr. G. W. Grabham, Government geologist, for much valuable information as to the sudd.

NOTE ON AN EXPLOSION DURING THE SEPARATION OF POTASSIUM BY THE PERCHLORATE METHOD.

BY A. F. JOSEPH, D.SC., F.I.C., AND F. J. MARTIN, M.A.

In the course of the examination of the Nile sudd (*cf. ante*) it was necessary to determine the total amount of sodium in papyrus ash. The sodium was brought into solution by fusion with potassium carbonate and extracting with water, the solution then containing potassium in excess, sodium, phosphates, and silica. After removal of the latter in the usual way, the phosphate was precipitated by ferric chloride and ammonium acetate, the filtrate evaporated to dryness, and the residue ignited to expel ammonium salts. The potassium was then

separated as perchlorate and the sodium estimated directly in the filtrate, as any method of determining it by difference appeared to be subject to too great an error, owing to the relatively large amount of potassium present.

The process was carried out as follows: After the removal of the silica the solution was evaporated two or three times with a slight excess of perchloric acid and the potassium perchlorate separated in the usual way. The filtrate and the alcohol washings, containing the sodium and excess of perchloric acid, were evaporated in a beaker nearly to dryness, and then transferred to a porcelain crucible, the evaporation being finished on an electrically heated hot-plate. The residue was treated with sulphuric acid and the sodium finally weighed as sulphate. A number of estimations in this manner were made without mishap. On the last occasion, however, a violent explosion occurred during the evaporation on the hot plate, when only 1 or 2 c.c. of liquid remained in the crucible. The force of the explosion produced a shallow cavity in the heavy top of the iron hot-plate over $\frac{1}{4}$ in. deep, the crucible being completely shattered and splinters driven with considerable force to a distance of 30 or 40 ft. Some of these splinters actually punctured bottles, flasks, and windows several yards away with holes about 1/10 in. diameter. Vessels close to the explosion were of course completely shattered.

The only cause we can suggest for this explosion is that some organic matter derived from the alcohol was not removed in the first part of the evaporation, and remained until the perchloric acid was concentrated. We have for the time being discontinued the use of this method.

Meeting held at Birmingham University on Thursday, February 12, 1920.

DR. H. W. BROWNSDON IS THE CHAIR.

CATALYSIS FROM AN INDUSTRIAL STAND-POINT.

BY E. B. MAXTED, PH.D., D.S.C.

THE discovery of new catalytic processes and of suitable catalysts has necessarily been made by the purely empirical method of trial and observation, except in so far as the choice of a probable catalyst was guided by analogy with known reactions. And the same is true regarding the study of catalyst poisoning, which, from an industrial standpoint, is almost of equal importance to that of catalysis itself.

While, however, the fruits of this purely experimental study are indisputably great, the systematic and intensified development of catalysis in the future depends on a better understanding of the theoretical principles which underlie the mechanism of the various types of catalytic processes.

In some cases, where catalysis appears to proceed by the purely chemical participation of the catalyst in the reaction, it is possible to carry out the process in stages, in such a way as to obtain a clear insight into what takes place under conditions such that the intermediate products are incapable of stable existence and the catalysed reaction consequently proceeds to completion, as, for instance, in the case of oxides of nitrogen in the chamber process for the manufacture of sulphuric acid, or the catalytic production of hydrogen by the interaction of water-gas with steam in the presence of iron. Whether this latter reaction takes place catalytically in one stage or by alternate oxidation and reduction, the contact mass emerges from the reaction in the same condition chemically as in the commencement, but fundamentally altered in physical structure.

In other cases, such as where the above reaction is catalysed by means of platinum, the rôle played by the catalyst is not so easily investigated by resolution into a series of changes and the effect observed may possibly be attributed to effects of a physical nature, especially since the reaction may also be catalysed to a certain degree by the mere presence of porous bodies, such as unglazed porcelain.

Thus a general theory of catalysis, which shall apply universally to every type of reaction is probably impossible, and each reaction, and, indeed, each catalyst employed for a given reaction, must receive special consideration with the object of setting up certain types of accelerating mechanism, for each of which separate theoretical principles will be involved. This is the necessary preliminary to the prediction of the degree of activity of a catalyst for a required reaction at a given temperature. A welcome step towards this goal has recently been made by Lewis in the application of the quantum theory of radiation to catalysis in general.

Catalysis in heterogeneous systems can only proceed provided that the required preliminary association of the catalyst with the reacting system can take place freely. Suspension of such free association will result in an effect similar to that observed in the presence of a catalyst poison, e.g., in the hydrogenation of an unsaturated glyceride with palladium at a temperature sufficiently low for the stearine produced to remain in a solid form on the surface of the palladium and thus gradually to

obstruct the free participation of the catalyst in the chemical change required, a "poisoned" curve being obtained.

A slightly more complicated example of the same type of inhibition is to be found in cases where the preliminary occlusion of one or more of the reacting substances is necessary before catalysis can proceed. Thus, in catalytic hydrogenation all the catalysts usually employed occlude hydrogen to a greater or smaller extent, and, with any given catalyst, catalytic activity and occlusive power appear to run more or less hand in hand, for catalyst poisons, such as hydrogen sulphide, not only destroy the activity of palladium but also its power of occluding hydrogen.

While the catalytic activity of the various metals does not vary directly as their occlusive power for hydrogen, what is ordinarily understood as occlusive power refers to the power of absorption at room temperature. As far as can be seen, no work has yet been carried out on the quantitative relation between the true activity of metals and the content of occluded hydrogen. If the function of the occluding metal is merely to render hydrogen available in the occluded condition, the catalytic activity of the preparation should, *ceteris paribus*, be proportional to the hydrogen content. If this is not so, the occluding metal itself, in addition to reducing the hydrogen to an active state, must itself take a part in the series of changes involved. Suspension of the occluding power should thus entail a suspension of catalytic activity and *vice versa*.

Paal and his collaborators have shown that palladium or platinum precipitated on metals such as lead, aluminium, silver, etc., is inactive. Mercury, which also acts as a catalyst poison, actually caused the evolution of hydrogen when brought into contact with palladium charged with this gas.

The poisoning of a catalyst for a desired reaction may be also caused by the presence of impurities such that the possibility exists of a second reaction, which may then take place in preference to that required. An example of this is the inhibitive effect of the presence of sulphur vapour in sulphur dioxide undergoing oxidation to trioxide in presence of platinum, oxidation of the sulphur taking place with partial inhibition of the reaction between sulphur dioxide and oxygen. It is, in general, typical of poisoning effects due to preferential reactions that the catalyst regains its normal activity on being subsequently used for pure reactants.

On thermodynamical grounds it may be shown that if the equilibrium point of a reverse reaction is independent of the presence or absence of catalyst, the activity of the catalyst for a given reaction must be the same as for the reaction when carried out in the reversed sense. Thus iron, which is active for the synthesis of ammonia, is also active for its decomposition, while nickel or palladium may be employed both for the synthesis of hexahydrobenzene from benzene and hydrogen or for the decomposition of hexahydrobenzene into its constituents. In the same way the principle may be extended to promoters and to poisons. For example, when ammonia was passed through an iron tube activated with potash the decomposition was four times as great as with the same tube unactivated. Similarly, on passing ammonia containing hydrogen sulphide through a similar unactivated tube, only about one-fifth as much decomposition was obtained as with pure gas. It does not follow, where more than one reaction can proceed simultaneously from the same reactants, that each of these reactions shall be equally accelerated by the presence of a given catalyst; indeed, one of the most important uses of catalysis in industry is for the preferential acceleration of what may be under

non-catalysed conditions the less important of two parallel reactions.

A typical example of this is given by Sabatier and Mailhe's work on the decomposition of formic acid in the presence of various contact bodies, these being grouped as dehydrogenation or dehydration catalysts respectively, according as the decomposition is represented by $\text{H.COOH} = \text{H}_2 + \text{CO}_2$, or by $\text{H.COOH} = \text{CO} + \text{H}_2\text{O}$. Copper or nickel, and the oxides of metals like zinc or tin, were found to give rise to hydrogen and carbon dioxide, while with, for instance, titanium dioxide decomposition into water and carbon monoxide occurred.

The catalysts may be grouped in such a way as to summarise their activating properties and the conditions under which these are exhibited. Such a tabulation is the only way in which it is at present possible to predict to some degree the most suitable catalyst for a required reaction.

The first great group comprises those substances which possess the power of activating hydrogen and are consequently of service both for catalytic hydrogenation and dehydrogenation. The temperature and the nature of the reaction will determine which catalyst is likely to be most suitable.

The platinum metals, generally, activate hydrogen readily at the ordinary temperature, and may be used for reactions in solvents where the temperature cannot be raised to that required for the base metal hydrogenation catalysts, this low temperature being also conducive to the absence of by-products. Thus, while the hydrogenation of benzene according to the original Sabatier method is always accompanied by considerable decomposition, the same reaction proceeds in presence of palladium or platinum at lower temperatures without any undesired secondary effects. Nickel does not usually begin to exhibit activity until well above 100°C ., but between about 150° and 350° it is a cheap and active catalyst for many reactions, e.g., the hardening of oils. Cobalt requires a higher temperature than nickel and is also less active, while with iron these two factors are even more pronounced than with cobalt. Iron is indeed specially useful for reactions at a comparatively high temperature, for instance 500° – 600°C ., at which it is often more efficacious than nickel, the activity of which is to a large degree destroyed by sintering when exposed to temperatures much over 400° . The successful use of iron for reactions such as the synthesis of ammonia is probably due to the fact that it activates nitrogen as well as hydrogen. Copper is a somewhat less violent hydrogenation catalyst than nickel. For example, Sabatier found that in hydrogenating styrolene with copper as the contact body the side chain only was reduced with production of ethylbenzene, whilst with nickel the benzene nucleus also underwent hydrogenation, ethylhexahydrobenzene resulting. Again, normal amylacetylene $\text{CH}_3(\text{CH}_2)_4\text{C}:\text{CH}$ with copper gave normal amylethylene, while with nickel heptane was produced.

With all the above base metal catalysts the temperature of preparation (usually by the reduction of their oxides by hydrogen) plays a great part in determining their activity, it being found that, above a certain minimum temperature, a low reduction temperature is conducive to high activity. All these catalysts probably depend on initial occlusion of hydrogen for their action, possibly followed by the chemical participation of the catalyst in the reaction, poisoning taking place usually either by the inhibition of this occlusive power or by reason of a preferred reaction.

The oxygen-activating catalysts are concerned with many important industrial operations, such as the oxidation of sulphur dioxide to trioxide and of ammonia to nitric oxide, the use of siccatives for drying oils, and the induction of surface combustion. Two distinct classes appear to exist, the first,

typified by porous porcelain and possibly by platinum, operating probably by physical means, at any rate as a preliminary; the second, catalysts which, as far as can be seen, operate by cyclic changes.

Of the oxidation catalysts of the first class platinum is probably the most generally applicable, being employed *inter alia* for the oxidation of sulphur dioxide to trioxide, of ammonia to nitric oxide, and, generally, for the catalytic oxidation of organic compounds of the most varied nature in the Dennstedt method of elementary analysis. It has been shown that the heat of occlusion of oxygen by platinum is of about the same magnitude as the heat of formation of platinum monoxide, but no proof exists that this oxide is an intermediate product during catalytic oxidation.

The second class of oxidation catalysts consists almost exclusively of substances which possess the property of forming higher oxides, which, in order that the catalysed reaction may proceed to completion, must, if they are formed as intermediate products, be unstable under the conditions employed for the reaction, these conditions including the presence of the substance to be oxidised. An example of this class of activator is to be found in nickel or cobalt oxide when used to evolve oxygen from bleaching powder. Cobalt forms an oxide CoO_2 , which may be prepared by the action of iodine and an alkali on a cobaltous salt, but which is unstable under the conditions employed for the evolution of oxygen by the reaction in question. Other examples of this class are to be found in manganese, cobalt, nickel, lead, or cerium salts when used for catalytically accelerating the oxidation of linseed and similar oils.

Nitrogen-activating catalysts have increased rapidly in technical importance during the past decade. Iron appears to be the most generally useful catalyst of this nature for reactions between 500° and 1000°C .; for instance, for the synthesis of ammonia and in the Bucher process for the synthesis of alkali cyanides. Iron does not form a nitride directly, although this can readily be obtained by interaction with ammonia. Other examples of nitrogen catalysis, the mechanism of which is not easily understood, are to be found in the acceleration of calcium cyanamide formation by calcium chloride, and the remarkable activity of osmium in causing the union of nitrogen and hydrogen.

The catalytic acceleration of hydrolysis and esterification by means of hydrogen ions is of considerable technical importance. The most probable explanation of the mechanism involved in this case seems to be that recently advanced by Lewis on the basis of the quantum theory of radiation. A case of considerable interest in connection with the hydrolysis of substances insoluble in water is the commercial hydrolysis of glycerides by means of the Twitchell reagent, which is soluble in oils and in water, and at the same time supplies the hydrogen ions necessary for hydrolysis.

A point of considerable interest arises in connection with catalysis generally, namely, the possibility of setting up a standard scale of activities on which it should be possible to express as a number the observed activity of a catalyst for a given reaction. Catalytic reactions in heterogeneous systems, especially gas reactions in the presence of solid catalysts, do not usually conform to the simple kinetic laws which obtain in homogeneous systems, and hence it is not always possible to take, as the "activity number" of the catalyst in question, the quotient formed by the reaction constant over the concentration of the catalyst, or some similar relation under standard conditions.

Similarly, the space-time-yield in heterogeneous gas reactions varies enormously not only with the

activity of the catalyst, but also with the velocity of passage of the reacting gases. If, however, for those heterogeneous gas reactions in which the gas passes over a solid catalyst, we take as the activity number at a given temperature and pressure the hourly output of product corresponding to unit weight of catalyst, with a standard space-velocity of gas flow, chosen in such a way that the time of contact with the catalyst is a convenient unit, a scale can be constructed which should be of considerable utility for the purposes required.

As an instance of the method of calculation the following examples may be cited. In the synthesis of ammonia, published data record a yield of 3.3 kilos. of ammonia per hour per litre of catalyst space, containing about 1.5 kilo. of iron/potash catalyst, the temperature being 580° C., the pressure 150 atm., and the time of contact one second, which for a slow process of the above nature may be taken as a convenient unit.

The activity number of the catalyst under the given conditions is thus: Hourly yield of product ÷ weight of catalyst = $3.3 \div 1.5 = 2.2$.

Where reactions take place at a comparatively high velocity a smaller unit of time than one second must be chosen for the standard time of contact, and there exist also numerous cases where more than one resultant is produced. In the latter case the activity number may be referred to the rate of production of any one of the products as required. For example, the production of hydrogen by the interaction of carbon monoxide and steam takes place with considerably greater velocity than the synthesis of ammonia, and for unit time of contact we may conveniently take 0.1 second. In an experiment to determine the activity number of an iron/soda catalyst at 500° C., carbon monoxide and steam in stoichiometric proportions were led through a 5 c.c. catalyst space, containing about 10 grms. of the iron/soda catalyst, at a rate calculated to give unit time of contact at 500° C. Hydrogen was found to be produced at the rate of 3.8 litres per hour, corresponding to 0.34 gm. The activity number of the catalyst, referred to hydrogen, under the conditions employed is thus:—

$A_{t=50} = \text{Hourly production} \div \text{weight of catalyst} = 0.34 \div 10 = 0.034$.

Finally, for reactions which proceed at extremely high velocities, such as the oxidation of sulphur dioxide to trioxide in presence of platinum, the standard time of contact may conveniently be reduced, for instance, to 0.01 second. Thus, on placing 0.48 c.c. of platinised asbestos, containing about 0.005 gm. of platinum, in the measuring apparatus employed for the last determination and passing sulphur dioxide and oxygen, in stoichiometric proportions, at 425° C., at a rate calculated to give a time of contact of 0.01 second, the rate of production of sulphur trioxide was found to be 27 grms. per hour. Calculating as before,

$A_{t=425} = 27 \div 0.005 = 5400$.

It is obvious that the activity number refers to the actual effect produced, and will vary considerably with the physical form in which the catalyst is employed. Further, for reactions of types other than those considered above, the same ratio between the weight of product formed per hour and that of the catalyst inducing the change, all under suitable standard conditions, may be taken as the activity number of the catalyst in question for the given reaction at the temperature employed.

DISCUSSION.

The CHAIRMAN said that the reduction of spelter from zinc oxide was a difficult reaction requiring much energy in the form of heat, and it was possible that the reaction might be cheapened by the use of a suitable catalyst.

Mr. L. P. WILSON said that catalysts had, as a rule, been employed in the production of cellulose

acetate for dope. Numerous catalysts had been suggested, including sulphuric acid, zinc chloride, bromine, phosphorus oxychloride, hydrazine, and sulphuryl chloride.

Prof. G. T. MORGAN agreed with the author that there was at present no possibility of any general theory of catalysis. The subject was much too complicated for a general theory to eventuate in the immediate future. The hypothesis advocated by van't Hoff and others that a catalyst was an agent which accelerated the velocity of the inverse change to the same extent as that of the direct change was, he thought, far from being generally proven. There were many cases in which this principle could hardly operate. Sabatier had stated that the hypothesis which had inspired him in his classical researches was that catalysis involved the formation of some intermediate compound. The speaker thought that this opinion still held the field in the majority of cases. It might be argued that it was improbable that intermediate compounds would be formed if, under the conditions of the reaction, they would be unstable; but that could hardly be postulated generally with regard to the transient existence of these substances.

The alkali metals with a large atomic volume were not so effective in certain catalytic operations as metals like platinum and copper having a small atomic volume, a circumstance which seemed to imply the intervention of residual affinity. A dilemma, which arose in regard to the intermediate compound when one considered the catalytic effect of porous materials, was the difficulty of determining where chemical action began and physical action left off. Strenuous efforts had been made recently to obtain a continuous process for making aniline catalytically from nitrobenzene and hydrogen, and extremely complex catalysts had been described. These facts tended to show that chemists in search of industrial catalysts still proceeded by a method of trial and error and not on any general hypothesis of catalysis.

Dr. T. SLATER PRICE said that many catalysts had been discovered purely by accident, as in the case of oxidation of naphthalene to phthalic acid; but in recent years undoubtedly there had been a tendency towards the opinion that catalysts in certain reactions should first be sought among metals which exerted different valencies. In connection with catalyses in homogeneous systems he thought there had been very definite progress in connection with the theory of the formation of an intermediate compound. It had been shown in quite a number of cases that this intermediate compound did exist and played the part which was assigned to it. Very often, because equations could be written assigning a definite rôle to an intermediate compound, it was supposed that an explanation of the catalytic effect had been given. But it was pointed out that such explanations were not valid until it could be shown that the velocity of the complete reaction was equal to the sum of velocities of the intermediate reactions postulated. That had been shown to be the case in a few instances and led to the belief in the general explanation. The question was raised as to the effect of a catalyst on the equilibrium attained, and Dr. Maxted referred to the usual thermodynamical proof that the equilibrium should be the same in the presence as in the absence of a catalyst. That had been proved experimentally in a number of cases where homogeneous systems had been investigated. The question, however, had been brought to the front again by Prof. Lewis, who had recently shown theoretically, by the application of the quantum theory, that it was possible for the equilibrium to be disturbed by the presence of the catalyst. Prof. Morgan had mentioned the probable connection between small atomic volumes and occlusive power. That did not agree, however, with the effect of sodium as a promoter in the

catalytic action of iron. The catalytic action of light had played an important part in the production of war chemicals, for example, in the manufacture of diphosgene (trichloromethyl chloroformate).

Dr. D. F. TWISS remarked that although there was a possibly natural tendency to propound various general theories as to the seat of activity in all catalytic substances, such generalisations would not bear close examination, and, at the present stage of investigation of the subject, were not particularly helpful.

Mr. F. R. O'SHAUGHNESSY endorsed the view expressed by Dr. Twiss, and pointed out that whereas the catalysts under discussion were inorganic bodies, active mostly at very high temperatures, the organic catalysts known as enzymes acted at low temperatures, and transformed masses of material under these conditions.

Mr. F. H. ALCOCK mentioned the case of the conversion of yellow phosphorus into amorphous phosphorus in presence of a trace of iodine.

Dr. MAXTED, in reply, said with regard to the point raised by the chairman, it was possible in some cases to lower reduction temperatures catalytically. For instance, it was possible to reduce copper oxide to copper at the ordinary temperature by the action of palladium; further, mixed oxides of nickel and copper were reduced by hydrogen at a lower temperature than nickel oxide alone. The production of cellulose acetate might not be a purely catalytic reaction, but to a certain extent an absorptive one. If only a little of the accelerating body were used it was catalytic. The evidence as to the atomic condition of hydrogen occluded by metals was based principally on the measurements of Sieverts and others on the relation between the pressure and the solubility of hydrogen. Regarding the time required for the penetration of hydrogen into the catalyst, and into the substance which was undergoing hydrogenation, the absorption was usually not so great quite at the beginning as subsequently. It took a short but appreciable time for the hydrogen to enter the liquid and reach the surface of the catalyst. A falling-off in the activity of platinum following disintegration would not be expected if no poisoning took place; in fact, the disintegration itself might cause an increase in activity by increasing the catalysing surface. It was found that with pure gases under certain conditions the activity of the catalyst might increase after it had been used for a certain time, but that, of course, had nothing to do with disintegration.

THE PREPARATION OF CYANOGEN CHLORIDE ON A LARGE LABORATORY SCALE.

BY T. SLATER PRICE, O.B.E., D.SC., AND STANLEY J. GREEN, M.A., A.I.C.

Examination of the literature on the subject* indicated that three methods might be feasible for preparing large quantities of cyanogen chloride, namely, the action of chlorine upon (a) hydrocyanic acid, (b) sodium cyanide, or (c) the complex cyanide of sodium and zinc.

Action of chlorine on a solution of sodium cyanide.

In this method, first suggested by Langlois,† considerable heat is evolved, and unless adequate cooling is employed the solution soon darkens in colour.

Experiments were also made with a modification proposed by Jennings and Scott (*loc. cit.*), using carbon tetrachloride as diluent, with 5000 grms. of sodium cyanide*; chlorine was introduced at the rate of about 2 litres per minute, and refrigeration approximately kept pace with the heat development of the reaction. A higher rate of passage of chlorine could not be used without a rapid rise in temperature taking place. The time necessary for the chlorination of the 5000 grms. of sodium cyanide would thus be from 19–20 hours, unless the refrigeration could be greatly improved. On a large scale such an improvement would be very costly, especially since the reaction mixture is not homogeneous.

A further point is that the reaction consists partly in the conversion of one solid (sodium cyanide) into another (sodium chloride), so that for quick reaction the sodium cyanide would have to be finely ground and vigorous agitation during chlorination would be required.† Calculations from thermochemical data show that in the production and condensation of one ton of cyanogen chloride the refrigerating plant would have to account for the absorption of at least 2,160,000 C.H.U.‡

Action of chlorine on the complex cyanide of zinc and sodium.

This method was first suggested by Held§ in 1897, the idea being that the addition of zinc sulphate to a solution of potassium cyanide made the solution more stable to the action of chlorine.

In our experiments sodium cyanide was used in place of potassium cyanide, the quantities of sodium cyanide and zinc sulphate taken being such that the compound $2\text{NaCN} \cdot \text{Zn}(\text{CN})_2$ was formed. In some cases to ensure a non-alkaline reaction mixture the mixture was such that a slight excess of zinc cyanide remained in suspension. The method gave fairly good results (compare Mauguin and Simon, *Comptes rend.*, 1919, 169, 383), but in view of the fact that it seemed to be much less economical and convenient than the one about to be described, it was abandoned. Jennings and Scott (*loc. cit.* p. 1244) also report adversely on the method.

Action of chlorine on a dilute solution of hydrocyanic acid.

Cyanogen chloride was first prepared in 1787 by Berthollet|| by the interaction of chlorine and hydrocyanic acid, and this method has since been the subject of many investigations (for literature references, see Jennings and Scott, *loc. cit.*). In all cases, however, the experiments were on a comparatively small scale, so that for our purpose it was necessary to carry out an extended series of trials before a satisfactory method of working was obtained.

The use of anhydrous hydrocyanic acid is impracticable for various reasons. For example, during the reaction hydrogen chloride is formed and polymerises any cyanogen chloride formed to cyanuric chloride. Also, the heat of reaction is so great that the temperature rises rapidly, in spite of vigorous cooling, and unchanged hydrocyanic acid, together with hydrogen chloride and any cyanogen chloride formed, distil over.

Tests showed that comparatively weak hydrochloric acid (about 2N–5N) had very little polymerising

* Jennings and Scott used only 50 grms.

effect on cyanogen chloride. Experiments were, however, first made with a 20% solution of hydrocyanic acid, the reaction mixture being cooled during the chlorination. It was intended then to separate the cyanogen chloride layer, but it was found that the aqueous layer increases in density, whilst the cyanogen chloride dissolves hydrocyanic acid and water, so that its density is lowered. Consequently the crude cyanogen chloride separates, sometimes above and sometimes below the aqueous layer. If chlorination were carried to completion cyanogen chloride should always separate at the bottom, but it is difficult to chlorinate completely without using excess of chlorine, which would carry much cyanogen chloride with it. All experiments in which a current of gas passed through the apparatus gave very bad yields. It was finally decided to employ a strength of hydrocyanic acid solution, such that at the end of the reaction the concentration of the hydrochloric acid formed is sufficiently below the saturation point to prevent much hydrogen chloride gas passing off: 12–15% hydrocyanic acid was found to be fairly satisfactory.

The reaction vessel was not cooled, the heat of reaction being utilised to distil off the cyanogen chloride as it was formed, so that it was quickly removed from the action of the hydrochloric acid set free at the same time. The heat of reaction is:

Porous pot water filters, suitably bunged and strengthened, and connected by glass tubing with the source of chlorine, were placed in the hydrocyanic acid solution and chlorine forced through under the pressure from a cylinder of liquid chlorine. The chlorine escaped in very fine bubbles and chlorination was extremely rapid.

Cyanogen chloride soon distilled and was condensed in two vessels containing water or dilute hydrocyanic acid (2%) and well cooled by brine. Absorption of chlorine takes place very rapidly, and the current of chlorine is so adjusted that no gas escapes at the end of the apparatus. The speed of chlorination in all experiments is so great that the rate of production of cyanogen chloride is determined by the rate of its condensation, and not by the rate of absorption of gas by the acid. In a typical experiment 7.35 litres of 12.2% hydrocyanic acid was chlorinated, the reaction vessel not being cooled. The cyanogen chloride was collected in water. The temperature rose quickly to about 30° C. and then ceased to rise. Chlorination was continued for 1 hour 50 mins., by which time much chlorine passed unabsorbed through the apparatus. It was assumed that this indicated the end of the reaction, but analysis showed that this was not really the case. The contents of the two receivers were added together and well mixed, after which the two layers, which separated on standing, were analysed. The total weight of cyanogen chloride formed from the 897 grms. of HCN used was 698 grms., corresponding with 79% of the theory. The cyanogen chloride layer formed in the receivers still contained more than 10% of hydrocyanic acid, although chlorine was passing all the time. By maintaining a low temperature in the reaction vessel the amount of hydrogen cyanide carried over into the receivers could be diminished, but this would also hold back a considerable quantity of cyanogen chloride and thereby cause it to be acted upon by the hydrochloric acid formed in the reaction.

In another experiment 7460 c.c. of 14.7% HCN was chlorinated, without cooling. The first receiver contained 970 c.c. of 2.21% HCN and the second contained water. Hence the total weight of hydrocyanic acid used initially was 1119 grms. After chlorination for 3–4 hours, the contents of the reaction vessel and the two layers obtained by

mixing the contents of the receivers were examined analytically, with the following results:—

	HCN		CNCl		HCl	
	Vol. c.c.	%	Wt. (grms.)	%	Wt. (grms.)	%
Reaction vessel	6300	0.76	48	2.0	126	13.9
Receivers—						
CNCl layer	1510	22.4	338	78.4	1184	Trace
Aqueous layer	1750	5.09	89	5.3	93	0.27
Total weight ..	—	—	475	—	1403	—

Correcting these figures for samples withdrawn for analysis, it appears that at the end of the experiment there were 495 grms. HCN, 1423 grms. CNCl, and 896 grms. HCl. The amount of HCN used is therefore 1119–495=624 grms., and the amount of CNCl equivalent to this is 1421 grms.

In another experiment carried out under similar conditions, and in which the temperature rose to 40° C., the total weight of cyanogen chloride was 97% of the theoretical.

The results of these and other experiments indicate that during the chlorination of 12–15% HCN cyanogen chloride is formed quantitatively according to the equation already given. A rise in temperature up to 40° C. does not diminish the amount produced; it does, however, lead to the distillation of much larger quantities of hydrogen cyanide, with a consequently higher content of this acid in the cyanogen chloride obtained. The hydrochloric acid formed during the reaction is retained almost completely in the reaction vessel.

The hydrogen cyanide contained in the cyanogen chloride can be approximately completely changed into the latter compound by bubbling the crude gas through a series of vessels containing water through which chlorine is also passed.

Further experiments were carried out in which the hydrocyanic acid was formed *in situ* from a mixture of sodium cyanide and mineral acid. In such a method the solutions must be dilute and the temperature not too low, and the mineral acid must be kept in excess. In the manufacture of hydrocyanic acid we have found that it is necessary to add the sodium cyanide solution to the acid, stirring vigorously meanwhile, otherwise pockets of alkaline liquid may be formed and give rise to polymer.

A method was also considered in which sodium cyanide solution is added to a dilute acid, say about 5%, until nearly the equivalent of sodium cyanide has been introduced. Chlorination then leads to the regeneration of the acid, so that sodium cyanide solution can be run in continuously during chlorination if the rate of running in is so regulated that the acid remains in excess. One difficulty with such a method was found to lie in adequate cooling of the reaction mixture, since both the reactions occurring are strongly exothermic, whilst on a large scale it is also difficult so to regulate the rates of addition of sodium cyanide solution and chlorine that the reaction mixture always remains acid. In the experiments where hydrocyanic acid was first made *in situ* and then chlorinated the solution of hydrocyanic acid was made in a carboy of 40–50 litres capacity, containing a cooling coil. The chlorine was introduced through a porous pot, as in previous experiments. Two Winchester bottles containing 2% HCN and water respectively were not cooled, but served to remove excess of chlorine and also some of the hydrocyanic and hydrochloric acids. The cyanogen chloride passed through these Winchester bottles and was condensed in a long, brine-cooled coil, being then col-

lected under water containing a little zinc oxide in suspension in order to neutralise any acid.

Chlorination was maintained at such a rate that the contents of the carboy kept below 20° C. Under these circumstances, once the air had been displaced from the apparatus, no gas or vapour passed from the exit tube of the apparatus. Chlorination proceeded very rapidly, and cyanogen chloride condensed in a continuous stream.

In one experiment 15 litres of 20% sodium cyanide solution was added to 15 litres of 21% sulphuric acid contained in a carboy, under continuous stirring and cooling. The strength of the hydrocyanic acid solution produced was 5.82%. After chlorinating for two hours the cyanogen chloride layer was collected, the various layers mixed, and analyses made. The results showed that the total weight of cyanogen chloride formed was 3022 grms., or 80% of theory. The presence of leaks probably explains the low percentage total production of cyanogen chloride. It is difficult adequately to seal a carboy so that it will stand a slight pressure over some hours without showing signs of leakage. There was only a very small quantity of ammonium chloride formed, which was found as a deposit in the condenser coils.

In a similar experiment where 30% solutions of sodium cyanide and sulphuric acid were mixed, giving a 9% solution of hydrocyanic acid, the yield was only 70% of the theory, and larger quantities of ammonium chloride were formed. Moreover, the cyanogen chloride collected contained 12% of hydrocyanic acid, as against only 1.8% in the above experiment. These results indicate that it is best to use dilute solutions, of about 5% strength, and not allow the temperature in the reaction vessel to rise above 20° C.

Purification of cyanogen chloride.

The cyanogen chloride obtained in the above experiments always contained water and hydrogen cyanide and also traces of hydrochloric acid. When it was not necessary to remove the hydrogen cyanide it was purified by distilling through columns of marble and calcium chloride, the former removing traces of acid and the latter drying the vapour. Shaking with water containing zinc oxide in suspension enables the column of marble to be dispensed with; the cyanogen chloride is simply separated, dried over calcium chloride, and distilled.

Three methods were actually used for purifying the cyanogen chloride, according to the purpose for which it was to be used:—

(1) Chemically pure cyanogen chloride was made on a small scale by cooling the crude substance, saturating with chlorine, shaking the product with (a) mercury to remove traces of chlorine, (b) sodium carbonate or sodium hydrogen carbonate* to remove hydrogen chloride, (c) drying over calcium chloride and distilling.†

(2) A product containing 96–99% CNCl was obtained by passing chlorine through a series of Winchester bottles containing 80–90% CNCl and a good excess of water, the cyanogen chloride thereby distilling in a current of chlorine. The condensed product sometimes contained chlorine in excess, and sometimes hydrogen cyanide, according to the purity of the original cyanogen chloride, rate of passage of chlorine, etc. This process can be applied in conjunction with the process of preparation, although in making large quantities of cyanogen chloride it was found more convenient to carry out the two processes separately.

(3) Shaking with zinc oxide was the practice when 99–100% CNCl was required. Prolonged shaking

with zinc oxide and water reduces the hydrogen cyanide content to 0.05%, and the product so obtained is then dried and distilled. Yellow mercuric oxide is also very convenient for removing even larger percentages of hydrogen cyanide.

The question may arise as to whether in the large-scale preparation (or manufacture) of cyanogen chloride it would be better to make the hydrocyanic acid *in situ*, or first prepare the pure aqueous solution. In the first method the solutions of sodium cyanide and acid used have to be well cooled before mixing, and extensive refrigeration must also take place during the reaction in order to prevent the hydrogen cyanide escaping. With the second method a brine-cooled condenser is only necessary to condense the last traces of vapour, the greater part being condensed in a water-cooled condenser. The demands on a refrigerating plant are therefore very small, and this second method would seem to be preferable. If an aqueous solution of hydrocyanic acid is all that is necessary, there will probably be no need for a brine condenser, so that no special refrigerating plant will be required.

Properties of cyanogen chloride.*

The pure product was a colourless liquid, boiling sharply at 13° C. (uncorr.). Jennings and Scott (*loc. cit.*) give the b. pt. as 13° at 748mm. The freezing point was -8° (Jennings and Scott give -5° to -6°; Regnault gives -7.4°). On pouring the liquid from one vessel to another it froze readily to a snow-like solid. Sp. gr. at 9°/4° = 1.207 and at 4°/4° = 1.218. Analysis gave N 22.7% and Cl 57.8%, theory requiring 22.8% and 57.7% respectively.

Cyanogen chloride is soluble in water to the extent of 7–8% at 8° C. Water is also soluble in cyanogen chloride; the presence of hydrogen cyanide markedly increases these mutual solubilities.

Investigation of the action of hydrogen chloride on cyanogen chloride shows that the following effects are produced:—(a) The cyanogen chloride is polymerised to cyanuric chloride, (CNCl)₃, a reaction which takes place slowly, and, apparently, only to any extent in the absence of water; (b) hydroxylation of the cyanogen chloride to cyanic acid and carbon dioxide, and hence to ammonium chloride and carbon dioxide. This is a much more rapid reaction than (a), and naturally requires the presence of water. Hydroxylation increases in rapidity with the strength of the acid, the action being complete in a few hours with 9N hydrochloric acid. With 2N acid the reaction is very slow, and even with 5N acid takes several days.

Pure cyanogen chloride has been kept for months without showing any signs of polymerisation; even exposure to sunlight for several days has no apparent effect. If traces of water are present a few minute crystals of ammonium chloride are soon deposited on the sides of the containing vessel, but if then poured into a clean dry vessel it can apparently be kept indefinitely.

In agreement with Jennings and Scott (*loc. cit.*) we have not found that dry chlorine has any polymerising effect on cyanogen chloride. With moist chlorine there is a slow action, but no polymer is formed, the action being simply due to the water present.

We have, furthermore, found that pure anhydrous phosgene and cyanogen chloride do not react. In the presence of moisture, however, both ammonium chloride and cyanuric chloride are formed.

ADDENDUM.

Some experiments with a small scale continuous-running apparatus were devised and carried out by Mr. S. B. Phillips. The apparatus was so arranged

* The use of sodium hydrogen carbonate is to be preferred, since it is not alkaline, and the cyanogen chloride is therefore more stable in its presence if water is present.

† This method was worked out by Mr. H. D. K. Drew, M.Sc.

* This work was mainly carried out by Mr. H. D. K. Drew.

that chlorine and a solution of hydrocyanic acid were brought together continuously, in approximately the correct proportions, and the cyanogen chloride formed was separated quickly from the reaction product.

The chlorinating part of the apparatus consists of a brine-cooled tower up which a steady stream of 10–12% HCN gradually flows. Chlorine is forced in through a porous pot fitting loosely into the lower end of the tower, the hydrocyanic acid solution passing through the annular space separating the porous pot from the walls of the tower. The remainder of the tower is filled with beads. As hydrocyanic acid solution flows into the bottom of the tower, the products of reaction overflow at the top, and are there impinged on by a good jet of steam. Cyanogen chloride is thereby vaporised, the vapours passing to a condenser and receiver. The exhaust reaction mixture is collected separately.

In one experiment with 15% hydrocyanic acid solution the product contained 99% of cyanogen chloride and less than 0.2% of hydrogen chloride. In a second experiment 4 litres of 8.9% hydrocyanic acid was run through the apparatus in two and a half hours. The temperature in the tower rose to 15° and remained constant. The product collected contained 95.7% cyanogen chloride and amounted to 70% of the theoretical.

It was not possible to work this method out in further detail, but we are of the opinion that it could be made to give very good results.

ACKNOWLEDGMENTS.

We are indebted to the Admiralty for permission to publish this paper, which is a record* of work on cyanogen chloride carried out under our direction at the Royal Naval Experimental Station, Stratford, E., during the war. We have also to express our indebtedness to a number of service subordinates, who carried out much of the experimental work involved, especially to Mr. W. Auger, B.Sc., A.R.C.S., who was Chief Petty Officer of the laboratory staff.

THE PROPERTIES OF POWDERS.

PART I.—THE CAKING OF SALTS.

BY T. MARTIN LOWRY AND FREDERICK C. HEMMINGS.

1.—THE STUDY OF POWDERS.

Although much attention has been paid to the general properties of solids, liquids, and gases, and also more recently to the study of matter in the disperse or colloidal condition, the study of powdered solids has received less attention than its importance would appear to demand.

The properties of powders which merit consideration include:—

(1) The production of powders by *mechanical disintegration* or milling, and especially the process of *fine grinding*, which has been studied much less fully than that of disintegration or rough grinding.

(2) *Disintegration by physical processes*, e.g., the decrepitation of barytes by heat, which has been applied commercially to separate it from blende and other minerals, and the change of crystalline state which makes roll-sulphur brittle, and which certainly assists in the disintegration of ammonium nitrate.

(3) *Disintegration by chemical processes* such as the hydration of quicklime and the dehydration of certain hydrated salts.

(4) *Methods of testing* the fineness of powders produced by these three methods, and especially of those which will pass through the finest sieves on which trustworthy measurements can readily be made.

(5) *Incorporation* of mixed powders as in the milling of gunpowder.

(6) *Bulk density* of a powder, as influenced by its method of preparation and subsequent treatment, and the choice of suitable grades to produce a maximum or a minimum density.

(7) The *compressibility* of powders both towards static loads and under impact.

(8) The *flow* of powders, including the special case in which a powder, such as dried milk, is packed into a bottle or some similar receptacle by the action of a worm-feed.

(9) The *shrinkage* or contraction which takes place in some powders, such as soap powders, after they have been packed into a container; and finally,

(10) The *caking* of a powder to form either a loose agglomerate or a hard stony mass as discussed in the present paper.

2.—GENERAL CAUSES OF CAKING.

A preliminary account of the work which we had carried out on the caking of salts between September, 1915, and December, 1917, was communicated to a meeting of the Faraday Society on Jan. 14, 1918, as part of a general discussion on the "Setting of Cements and Plasters." At the same time some of the principal causes of caking were set out by F. G. Donnan in a paper on the "Agglomeration of Granular Masses," the conclusions arrived at being substantially identical in the two cases.

The agreed causes of caking in soluble salts may be summarised as follows:—

(i.) *Evaporation of moisture* from a wet salt, or alternate absorption and evaporation of water as the pressure of water-vapour in the atmosphere rises above and falls below the vapour-pressure of a saturated solution of the salt. The further lowering of vapour-pressure due to saturation with a second salt or impurity (e.g., $MgCl_2$ in $NaCl$) may be an important factor in bringing the vapour-pressure of the solution within the normal range of variations of the moisture-content of the atmosphere.

(ii.) *Mechanical stress* or pressure resulting in a local increase of solubility in the strained material followed by recrystallisation elsewhere.

(iii.) *Recrystallisation of fine particles* to form larger crystals, as in the prolonged annealing of a metal.

(iv.) *Recrystallisation of metastable crystalline forms* after passing through a transition-point; this may be related very closely to (iii.), since the pseudomorphs may consist initially of particles even more minute than those produced by grinding.

(v.) *Recrystallisation of amorphous material* produced by cold-working of the material.

In each case the presence of a trace of solvent may be postulated. Consolidation by pressing may depend on (ii.), where the solvent plays a predominant part, or on (v.) where shearing and flow may be fol-

* Owing to want of space this record has been considerably condensed for the purposes of publication.

lowed by cohesion even when no solvent can be detected.

3. THE CAKING OF AMMONIUM NITRATE.

Our attention was first directed to the caking of powdered solids by observations made in the case of ammonium nitrate. This salt crystallises from aqueous solutions in long needle-shaped or prismatic crystals, which may run to a length of several feet when the salt is crystallising slowly in a large vat. These crystals carry with them a considerable proportion of moisture, not only on the surface, but in the interior, since the crystals are often tubular in character and contain long threads of mother liquor. When drained either by gravity or in a centrifugal machine a coarsely crystalline product is obtained in which the long needles are broken down into short lengths but otherwise remain intact.

(a) *Caking after drying.*—These crystals, if allowed to dry spontaneously in the air, bind together slightly as the mother liquor on the surface evaporates; but no very great cohesion is observed in the mass, which can easily be broken down again. A coarse, granular product can also be obtained by drying the crystals in a current of warm air at a temperature only slightly above that of the atmosphere. If, however, the wet crystals are dried in any of the ordinary commercial dryers, either by hot air or by contact with a steam-heated surface, the product when packed into barrels cakes together into a hard mass resembling artificial stone, which must be broken up with steel wedges. The contrast between these samples was most readily explained by the fact that the crystals dried at a low temperature retain their original crystalline form, whilst the samples dried by heat undergo a change of state by heating and cooling through 32°C .

(b) *Caking after grinding.*—Caking of an equally marked character occurred in ammonium nitrate which had been poured out in a molten condition, with a small percentage of water, at a temperature a little below the melting-point of the dry salt. On breaking up the rough slabs formed by casting, a product was obtained which did not bind together on storage; but when the slabs were disintegrated and packed whilst still warm, a very hard cake was produced. Some caking was also noticed when the fused product was disintegrated and packed cold. From these experiments it appeared likely that disintegration might also be a factor in promoting the caking of ammonium nitrate.

(c) *Caking after milling.*—Experiments were made to determine the effect of milling cold ammonium nitrate under the heavy rolls of an edge-runner mill. After milling for an hour and leaving under gentle pressure overnight, distinct caking was observed, although the temperature of the nitrate had not risen during milling to the transition-temperature at 32°C .

4. CAUSES OF CAKING OF AMMONIUM NITRATE.

(a) *Change of state.*—When ammonium nitrate is dried by heat, changes of state occur at 32° and at 84°C . The change at 32° is accompanied by an abrupt change in the texture of the nitrate, and even in a commercial dryer a slight arrest of temperature can sometimes be observed (Figs. 1 and 2). At this point the coarse crystals break down, either into brittle pseudomorphs, retaining the form of the parent crystal, or (when the drying is accompanied by agitation) into a snow-like mass which dries to a fine powder. The change of state at 84° is accompanied by a very marked arrest of temperature (see Figs. 1 and 2), but by no visible alteration of texture, as the snow-like mass has usually fallen to a dry powder before this temperature is reached.

Heating of 80 lb. of ammonium nitrate in a small Hind and Lund machine.

Fig. 1.

Heating of 600 lb. of ammonium nitrate in a large Hind and Lund machine.

Fig. 2.

It was thought at one time that disintegration rather than caking followed the expansion which accompanies the change of state on heating through 32° (or on cooling through 84°), and that caking as a result of change of state took place on cooling through 32°C . (and possibly on heating through 84°C), following upon contraction of volume. This view could not be maintained, however, in view of the fact that crystals which had been disintegrated by heating to a temperature between 32° and 84°C . formed an extremely hard cake within an hour or two after packing and probably a whole day in advance of passing through the transition-temperature of 32°C . From this observation it was clear that change of state might result in disintegration, but that it was likely to lead to caking only as a result of secondary changes.

(b) *Recrystallisation of fine particles.*—Whilst the view that change of state was a direct cause of caking could not be maintained, it appeared likely that the minute particles of the pseudomorph might tend to grow into larger crystals, just as in the case of a metal submitted to prolonged annealing, and that the growth of the fine particles might be accompanied by caking as a result of the obliteration of the original boundaries between them. This view was supported by the caking after disintegration of the slabs of cast ammonium nitrate referred to under 2 (b) above, since strong caking took place when the hot powder was allowed to cool through 32°, whilst a much less pronounced caking was produced by the mechanical disintegration of the cold slabs. The view that the production of fine particles, either by thermal treatment or by mechanical disintegration, was the principal cause of caking was, however, abandoned in its turn in view of the experiments described under (c) below.

(c) *Mechanical working.*—Mechanical working, leading to the formation of amorphous material, could not be regarded as a potent factor in promoting the caking of ammonium nitrate, since only slight caking was noticed after the disintegration of cold ammonium nitrate, whilst the agglomeration after milling under edge-runners was scarcely enough to enable the product to support its own weight.

(d) *Compression.*—Ammonium nitrate can be consolidated into very hard blocks by pressing. In this process the mechanical working is so much more severe than in disintegration or milling that the production and recrystallisation of amorphous material might play an important part in producing cohesion but even here any greater readiness on the part of the nitrate to consolidate in comparison with an insoluble compound such as calcium carbonate or barium sulphate, could be interpreted most readily as due to the increased solvent action of moisture on the particles supporting the stress of the plunger.

(e) *Liberation of moisture.*—The conclusion arrived at finally was that the key to all the observations that had been made on the caking of ammonium nitrate was to be found in the effect of drying, grinding, milling, etc., on the moisture in the salt. Conclusive proof of this was obtained when it was found that whilst commercial drying at a high temperature was always followed by caking, it was possible in the laboratory to carry the drying of the salt to a point at which it could be kept indefinitely as a loose powder under precisely those conditions which had been found to provoke the hardest caking. Indeed, during the latter part of the time when these experiments were in progress the absence of caking was found to be the most suitable test of the effective drying of samples required for use in other investigations.

(f) *Conclusions.*—The conclusions finally arrived at in reference to the causes of caking of ammonium nitrate were as follows:—

(1) Caking is not caused directly by change of state, but this gives rise directly only to disintegration and to liberation of moisture from the partially-dried crystals; the immediate cause of caking is then the cementing effect on the tiny particles of the disintegrated salt of moisture released during the change of crystalline form.

(2) Liberation of enclosed moisture can also be effected by mechanical disintegration, and this may give rise to caking in precisely the same way as the disintegration and liberation of moisture consequent upon change of state, although the effects are much less pronounced. In the absence of moisture mechanical disintegration would probably not give rise to caking.

(3) In an edge-runner mill the moisture is able to evaporate as fast as it is released by milling, a

fact that is frequently made use of as a convenient method of drying, e.g., in the manufacture of gun-powder; under these conditions the effect of the released moisture is only slight, and the mechanical working does not suffice to produce any serious caking of the salt.

5. EXPERIMENTS ON THE INFLUENCE OF MOISTURE.

The correctness of the views set out above was established by experiments which showed that caking after change of state could be stopped by drying. Supporting evidence was found (i.) in experiments which showed that disintegration of ammonium nitrate gave rise to liberation of moisture; (ii.) in the intimate relationship between solubility and caking which was established by experiments described in the later portions of the present paper; and (iii.) in the fact that, in other cases, mechanical working was proved to have little influence in causing caking except when a solvent was present.

(a) *Caking of ammonium nitrate prevented by drying.*—In order to obtain ammonium nitrate quite free from moisture, 30 grms. of the recrystallised salt was heated in a steam oven at 90° C. for ten hours, the hot salt being ground every hour; it was then left in a vacuum-desiccator overnight. On the following day it was heated again for two hours, during which it was ground every half hour. The salt was then sealed under a lead weight of about 70 grms. in a hard glass tube containing a little phosphoric anhydride kept in position by means of a plug of glass wool. Before sealing, the tube was heated in water at 80° C. and exhausted with a Gaede pump during eight hours, the weight being moved up and down to disintegrate the salt from time to time. After a month this sample of ammonium nitrate showed no tendency to "cake," and even at the end of a year the particles were still free; but so long as there was even a trace of water present agglomeration of the particles occurred.

(b) *Caking by evaporation of moisture.*—The loss of moisture from wet samples of ammonium nitrate is always accompanied by the caking of the salt; and when slight pressure was brought to bear upon the moist substance after packing, hard solid blocks were sometimes obtained. The hardness of the masses formed in this way was found to correspond roughly with the amount of water that had evaporated.

As indicating the importance of solubility in determining caking, reference may be made to the behaviour of ammonium nitrate that has been crystallised from alcohol. When a sample of this product containing about 3% of mother liquor was packed in a glass dish and allowed to stand, the alcohol evaporated, but the salt showed very much less tendency to "cake" than when crystallised from water, the difference being due presumably to the difference in the solubilities of ammonium nitrate in water and in alcohol.

(c) *Liberation of moisture after grinding.*—A sample of coarsely powdered ammonium nitrate that was packed in a mortar after having been exposed to a dry atmosphere was found to show very little tendency to "cake"; when, however, the fragments were ground for about 10 minutes and then repacked distinct "caking" took place. This process of grinding and packing was continued until there was very little evidence of further caking. The original crystals contained 0.24% of moisture; after the first grinding and period of quiescence the moisture-content was reduced to 0.18%, and finally to 0.09%. It thus appeared that one effect of grinding was to break down the crystal structure and to release the moisture that had been retained in the crystal; as this moisture was present as saturated solution, its evaporation would be likely to cause the salt to cake.

In a confirmatory experiment a single crystal weighing 19.963 grms. lost 0.151 gm., or 0.76% moisture by grinding and exposure to a dry atmosphere. In a further experiment some small air-dried crystals lost 0.084 gm., or 0.34% of moisture in a vacuum desiccator, and a further 0.54% after grinding; the amount of moisture trapped in the interior of the crystal and released during grinding (0.54%) was therefore half as much again as the amount of moisture (0.34%) originally present on the surface of the crystal, and released by mere exposure to a dry atmosphere.

(d) *Influence of moisture on caking of amorphous material.*—From the preliminary observations re-recorded in 2 (b) and (c) above, it seemed possible that the formation of amorphous material might play an important part in caking, as is almost certainly the case when blocks of ammonium nitrate are prepared by strong compression, e.g., with a hydraulic press. As it was not practicable to do any effective "cold-working" without introducing moisture to the dry salt, it was not possible to determine finally whether drying the salt would inhibit entirely the caking due to the formation and crystallisation of amorphous material; two simple comparative experiments on ammonium nitrate dried with and without phosphoric anhydride were carried out which, though not very conclusive, suggested that when the salt is not completely dried the effect of work in causing adherence is more pronounced than when drying is as complete as possible.

6. COMPARISON WITH OTHER NITRATES.

Assuming the caking of ammonium nitrate to be due to liberation of included mother-liquor as a result of disintegration by grinding or by change of state, it was to be expected that sodium and potassium nitrates would exhibit some similar phenomena, but in a lesser degree owing to their much smaller solubility in water, namely, ammonium nitrate 185.0, sodium nitrate 87.5, potassium nitrate 31.2 grms. per 100 grms. of water.

(a) These salts do, in fact, cake under much the same conditions as ammonium nitrate, e.g., after grinding, although change of state cannot be utilised as a method of disintegration. The amount of caking is considerably less in sodium nitrate than in the case of ammonium nitrate, and very much less in potassium nitrate. Sodium nitrate has usually to be quarried from a store in which it has been kept for a few weeks, and the lumps which have formed there are so hard that they have been known to break the axle of the machine used to crush them; caking during drying is also very severe, and under some conditions of working a rotary dryer may become so choked that sodium nitrate has to be removed with a pickaxe. At Messrs. Curtis's and Harvey's factories it is stated that potassium nitrate, crude or refined, also has a great tendency to cake, especially when moist or under the influence of heat or pressure. In each case it was found that caking was entirely prevented by drying the salt completely, as in par. 5 (a), and in manufacturing practice drying to about 0.1 to 0.2% of moisture is said to be sufficient to prevent caking on storage.

(b) An experiment was made to compare the amounts of mother-liquor retained by the three nitrates. Crystals which passed through a 4-mesh sieve but were retained on a 10-mesh sieve were weighed out into aluminium boxes and left in vacuum desiccators containing concentrated sulphuric acid, until the weights were constant. The crystals were then broken up from time to time until no further loss of weight could be detected. The final losses in weight were as follows:—Ammonium nitrate, 0.31%; sodium nitrate, 0.68%; potassium nitrate, 0.32%. These results show that the amount of caking that takes place must be deter-

mined by solubility rather than by the proportion of included moisture. It is also interesting to notice that ammonium and potassium nitrates, which both crystallise in the orthorhombic system, contain equal proportions of included moisture, whilst sodium nitrate, crystallising in the rhombohedral system, contains twice as much.

7. OTHER EXAMPLES OF CAKING IN COMMERCIAL PRODUCTS.

Although the caking of the nitrates described in the preceding paragraphs is of a particularly striking character, the same phenomenon is encountered amongst other compounds and is a frequent source of annoyance. In view of the widespread character of this trouble, an inquiry was made, with the financial assistance of the Department of Scientific and Industrial Research, into a number of cases in which difficulties due to caking had been experienced by manufacturers. The substances named as giving rise to trouble as the result of caking were ammonium, sodium, potassium, and copper nitrates, potassium chlorate and perchlorate, potash alum, soda ash, common salt, borax, sodium sulphite, hydrosulphite, and phosphate, Rochelle salt, citric acid and tartaric acid. The majority of these compounds were therefore examined in the laboratory, and in certain cases it was possible to make useful suggestions with a view to reducing the tendency of the salt to a cake.

8. EXPERIMENTS ON THE INFLUENCE OF SOLUBILITY ON CAKING.

Samples of various substances were taken from the laboratory store, ground to pass through a 60-mesh sieve, packed into stoppered bottles, and allowed to remain at rest. The substances examined were grouped as follows:—

(a) *Insoluble salts:* Barium sulphate, calcium carbonate (chalk, marble, calcite).

(b) *Soluble substances* selected to cover a considerable range of solubility: Ammonium, sodium, and potassium nitrates, common salt, sugar, potassium chlorate and perchlorate, potassium bichromate, calcium acetate (less soluble in hot water than in cold).

(c) *Hydrated salts* containing different amounts of combined water: Alum (24 mols.), borax, washing soda, and Glauber's salts (10 mols.), Epsom salts (7 mols.), Rochelle salt (4 mols.), citric acid (1 mol.).

On examining these specimens after six weeks it was found

(a) That the insoluble substances showed no tendency to cake;

(b) That all the soluble salts showed a tendency to cake, and that this tendency appeared to be related in some way to their solubilities;

(c) That the hydrated salts showed a distinct tendency to cake, but that the amount of caking did not appear to be related to the amount of combined water.

The view that water plays an important and perhaps a vital part in the caking of powdered salts was confirmed by experiments in which we attempted to produce caking in an insoluble compound. The substance selected for this purpose was calcite.

(i.) Crystals of this were ground to pass a 100-mesh sieve. The powder was packed in a crucible and allowed to stand in the air, but no signs of caking were visible at the end of three months.

(ii.) 2% of freshly-boiled distilled water was added during the grinding. At the end of a week all the water had evaporated, but there was no sign of caking.

(iii.) When water containing carbon dioxide in solution was used, a definite tendency to cake was observed, which increased as the amount of carbon dioxide in the water was increased.

(iv.) Smooth cleavage-surfaces of calcite, when rubbed together and allowed to rest in contact under a load of 500 grms. showed no tendency to adhere either when the faces were dry or when they were moistened with a few drops of water during the rubbing. When, however, water saturated with carbon dioxide was used, the crystals adhered appreciably.

9. CAKING OF POTASSIUM PERCHLORATE.

Potassium perchlorate for use in explosives requires to be in a very fine state of subdivision and is generally specified to pass through a 120-mesh sieve. It separates from solution in coarse crystals, which when ground in a ball-mill caked into a solid mass on which the balls run with very little grinding action. This caking was traced to the liberation of moisture during grinding, and by eliminating this the caking was prevented. The presence of moisture in samples that have not been dried after grinding may also be responsible for the growth of the grains of this salt during storage which has been reported frequently.

10. CAKING OF CITRIC AND TARTARIC ACIDS.

These two acids in the form of powder are liable to very serious caking. By grinding in a current of warm air and packing in oiled paper this trouble can be eliminated almost entirely.

II. THE CAKING OF CRYSTALLINE HYDRATES. ROCHELLE SALT.

Many hydrated salts give a great deal of trouble through caking, especially when they are ground before being packed. Complete removal of water from the powder before packing is usually impracticable on account of the difficulty of removing the last traces of solvent water without driving off also some of the combined water.

A typical case is that of Rochelle salt,

of which two samples were received. One of these was a fine powder, but the other, originally in the same condition, was now composed of hard solid lumps. It was stated by the manufacturers that after a long and careful series of titration tests they had been able to discover no difference in composition between the caked and uncaked samples. Experiments showed:—

(1) That there is practically no tendency for the salt to absorb or lose water under ordinary atmospheric conditions; but slight setting of a coarsely powdered sample was noticed after about 2 months' exposure to the air of the laboratory.

(2) That setting takes place in the usual way when excess of water is present. The water evaporates and crystalline material is deposited.

(3) That the crystalline salt disintegrates to a very fine powder when dehydrated slowly in a desiccator over sulphuric acid.

(4) That when water is absorbed by the powdered partially-dehydrated salt from air saturated with water-vapour there is distinct caking, accompanied by contraction.

(5) That the caking and contraction continue for some time after the amount of water needed for complete hydration has been absorbed.

From these observations it appeared that the setting might be attributed either (i.) to the escape of water from an imperfectly dried sample of the salt, or (ii.) to the absorption of water by the salt after being partially dehydrated. The commercial samples of the salt are, however, packed in tins provided with tightly fitting lids, and lined with water-proof paper, so that there is very little opportunity for either absorption or escape of water to take place; it is, moreover, difficult to reconcile either of these theories with the statement of the manufac-

turers that they have found no difference in hydration between caked and uncaked specimens of the same original salt. Some theory based upon redistribution, rather than actual loss or gain of moisture, is therefore required to provide a satisfactory explanation of the caking of the salt in the circumstances in which it actually occurs.

12. LIBERATION OF MOISTURE FROM HYDRATED SALTS DURING GRINDING.

In order to clear up this question experiments were made to determine the effects produced by grinding Rochelle salt. A minutely-crystalline sample of the salt was prepared, dried on a porous plate and exposed to the air until the weight was constant. The crystals were then well ground and weighed again immediately after grinding; the loss of weight was 5 mgrms., but after an interval of a quarter of an hour, and again on the following day the weight was the same as before grinding. The experiment was repeated with the same result. After grinding for another five minutes the total loss of weight was increased to 9 mgrms., and after further grinding 15 mgrms., or 0.07% of the weight of the salt; but on allowing the salt to stand for an hour the original weight was regained.

Similar results were obtained with potash alum. The loss was slightly greater than with Rochelle salt, and amounted to 0.09% of the weight of the salt, but the original weight was regained on standing. In the case of salts without combined water grinding releases included moisture, and the solvent that evaporates does not return, provided atmospheric conditions are constant; with the hydrated salts, however, the water that is lost during grinding appears to return during quiescence.

These experiments suggest that the effect of grinding Rochelle salt is to break down the molecule, so that some of the water that was previously in combination becomes free. Of the free water thus produced a small amount is given off as vapour to the air, but the part that remains in contact with the salt will become supersaturated with the lower hydrate, and from this solution crystals of the fully hydrated salt will be deposited on standing. In this way it is possible to explain why there is no difference in the amount of water present in the caked and uncaked samples of Rochelle salt; the very small amount of water that evaporates during grinding returns during packing and need not be specially taken into account in the process of caking. When the salt is packed after grinding the water is present partly in the combined state and partly as saturated solution; during the period of quiescence the water of the saturated solution is taken up to form crystals of the fully hydrated salt, and setting must necessarily accompany such a definite process of crystallisation. The actual amount of water present will, however, be exactly the same after as before caking. The principles here given no doubt hold good for other crystalline hydrates.

13. CONTRACTION DURING CAKING OF HYDRATED SALTS.

The contraction observed during the caking of Rochelle salt was noticed on several occasions when dealing with other salts, including potash alum, and was particularly noticeable in the case of copper sulphate. As this phenomenon has an important bearing on many problems connected with chemical industry, it was considered that the mechanism of the process was well worth investigation, especially as the contraction appeared to be related very closely to the caking. Copper sulphate was chosen for the investigation, and a careful study was made of the changes that take place during the hydration of this substance.

A quantity of the anhydrous salt, prepared by heating the pentahydrate to 240° C. in a crucible until the weight was constant, and kept in a desiccator over phosphoric anhydride, was weighed into a thick-walled crystallising dish, transferred to an atmosphere saturated with water-vapour, and weighed at intervals of 24 hours. The following observations were recorded:—

(1) The rate of absorption of water was greater in the system $\text{CuSO}_4\text{—CuSO}_4\cdot\text{H}_2\text{O}$ than in the system $\text{CuSO}_4\cdot\text{H}_2\text{O—CuSO}_4\cdot 3\text{H}_2\text{O}$; and greater in the latter than in the system $\text{CuSO}_4\cdot 3\text{H}_2\text{O—CuSO}_4\cdot 5\text{H}_2\text{O}$.

(2) There was very little change in the volume of the powder until after sufficient water for the formation of the monohydrate had been absorbed. After this point had been reached the mass began to swell up in a remarkable manner. The swollen mass was broken and levelled down periodically, but the swelling continued until an amount of water equivalent to nearly 4 molecules had been absorbed.

(3) When the hydrate had reached a point corresponding to the absorption of 4.95 molecules of water, setting and contraction commenced, the salt shrinking right away from the sides of the containing vessel. This point was marked by a great slowing down in the rate of absorption of water. The contraction continued until the amount of water present was equivalent to 5.1 molecules.

(4) On exposing these fully hydrated blocks to the atmosphere, water was given off, rapidly at first, but subsequently very slowly, until the amount present was almost exactly the same as when contraction commenced. The density of two of the blocks was found to be 2.02 and 2.05 respectively, the absolute density of $\text{CuSO}_4\cdot 5\text{H}_2\text{O}$ at 15° C. being 2.284.

(5) A sample of fully hydrated salt was ground and exposed again to a saturated atmosphere. Setting and contraction were apparent, but were much less intense than those observed previously.

(6) A sample of the salt was partially dehydrated and ground. Setting and contraction were observed at approximately the same point as before (4.95 molecules of water), but here, again the changes were not so marked as when the anhydrous salt was under consideration.

14. CAUSES OF CAKING AND CONTRACTION IN COPPER SULPHATE.

It is noteworthy that whereas anhydrous copper sulphate swells during hydration, up to about $4\text{H}_2\text{O}$, contraction and caking only occur when hydration is almost complete, namely, 4.95 molecules. At this stage the salt will consist almost entirely of the pentahydrate with a few particles of trihydrate. The latter will no doubt be found near the centre of the mass, and the water absorbed on the surface will therefore be present temporarily as a solution saturated with respect to the pentahydrate. When this comes into contact with the trihydrate this will dissolve to form a supersaturated solution, and crystallisation as pentahydrate will at once set in. Only when partially dehydrated salt and free water (as saturated solution) are present in the same mass does marked contraction or caking occur. Thus, when the partially dehydrated salt is in large excess there is no contraction because the water is directly absorbed by it; and, again, caking and contraction are only slight when the fully hydrated salt is exposed to a saturated atmosphere, because there is none of the trihydrate present to produce a supersaturated solution.

After caking in a saturated atmosphere is complete, the fully hydrated blocks of copper sulphate give up all their solvent water when transferred to an unsaturated atmosphere, and return practically to the composition at which caking began, namely, almost the theoretical composition of the pentahydrate.

As regards the mechanism by which contraction is produced during caking, it may be suggested that when the saturated solution of the pentahydrate comes into contact with the particles of trihydrate, the smallest particles will dissolve first and equilibrium will be restored by the growth of the larger crystals. This virtually resolves itself into a process whereby several small crystals are formed into one large one, and this may be a direct cause of the contraction which takes place. The amount of contraction that is possible will be determined in part by the amount of air space or "voids" originally present. The high density (approaching that of the crystal itself) obtained in the hydrated blocks of copper sulphate affords excellent evidence of the efficiency of the forces that are at work to produce contraction.

An incidental factor in determining the amount of caking and contraction is the original size of the particles. Attention may be directed specifically to the beautifully disintegrated products which are formed by dehydration, since these compare not unfavourably with the powdering of lime by slaking or the disintegration of ammonium nitrate by change of state. It is, indeed, very difficult to grind the fully hydrated salt to anything like the same degree of fineness as that to which the anhydrous salt was reduced. The same difficulty was experienced, though not nearly to so large an extent, in grinding a sample that had been partially dehydrated. It is therefore possible that the dehydration of the copper sulphate (like the change of state in ammonium nitrate) may owe much of its importance as a factor in causing caking to its efficiency in producing a more minute subdivision than can be reached by the mechanical grinding of the salt.

15. CAKING OF COPPER NITRATE.

This salt gives very great difficulties, due to caking. Below 24.5° C. it exists as a hexahydrate, $\text{Cu}(\text{NO}_3)_2\cdot 6\text{H}_2\text{O}$, but when this temperature is exceeded the salt begins to melt; crystals of the trihydrate separate at the bottom of the containing vessel, and the upper part is filled with solution; on cooling, crystals of the hexahydrate again separate, and a solid block is formed. Now, this temperature, 24.5° C, is often exceeded in the laboratory and factory. Direct sunlight easily brings about the decomposition of the hexahydrate, and so does grinding. It appears, too, that even the pressure of the substance, when packed in bulk, may be sufficient to bring about this change.

16. CAKING OF SODIUM BISULPHITE.

Sodium bisulphite cakes under rather peculiar circumstances, and (with the hydrosulphite described in the following paragraph) may be regarded as an illustration of a third type of caking, which is accompanied by and may indeed be caused by a chemical decomposition other than the mere gain or loss of water.

When sodium bisulphite is exposed to the air of the laboratory, it loses sulphur dioxide gradually, but there is little tendency to cake. When, however, it is placed in a confined atmosphere saturated with water-vapour, the loss of weight is more than thirty times as rapid, and under these circumstances the loss of sulphur dioxide is accompanied by hard caking of the salt. After a time gas ceases to be given off, the weight of the salt begins to increase as water is absorbed, and there is a slight softening of the mass.

The explanation of these changes is that the sulphur dioxide, being more than twice as dense as ordinary air, can only free itself from the bisulphite very slowly. Equilibrium is soon reached between the dissociation-pressure of the sulphur dioxide in the salt and the vapour-pressure of that which has been set free. When, however, the surrounding air

is saturated with water-vapour, the conditions of equilibrium are disturbed; the solubility of the gas (5000 volumes in 100) is enormous, and any sulphur dioxide set free from the salt is at once taken up by the water in the surrounding atmosphere, thereby opening the way for the release of more gas from the solid. That this decomposition of the salt actually takes place during caking was confirmed by the strongly acid reaction of the water in the vessel in which the experiment was conducted.

17. CAKING OF SODIUM HYDROSULPHITE.

Two samples of this substance of the same manufacture, and packed in 1 lb. bottles, were investigated. One bottle had been opened on several occasions, and in this the salt was in the form of a hard, rock-like mass. The other was as originally supplied, i.e., tightly corked and sealed with wax, and in this the particles were perfectly free.

Now the hydrosulphite can form a hydrate containing 2 molecules of water, and the formation of this from the anhydrous compound necessarily produces caking. The hydrate is, however, very unstable, and decomposes rapidly, giving off sulphur dioxide; this decomposition serves to increase the caking that has already commenced.

The granular commercial product is obtained by boiling the dihydrate with absolute alcohol to remove the combined water, the resulting anhydrous compound being comparatively stable. It is evident, therefore, that the caking of this substance is due to the formation of a crystalline hydrate and to subsequent decomposition of the salt.

18. METHODS OF PREVENTING CAKING.

The experiments on hydrated salts, together with those on dry ammonium nitrate, prove clearly that both caking and contraction can be avoided if all traces of free solvent are removed. The results obtained during the study of copper sulphate suggest that this can be accomplished very easily in the case of crystalline hydrates, since agglomeration would not be expected to take place in a dry atmosphere so long as there is a small amount of a lower hydrate present. Experiments were therefore made in which 5% of the trihydrate, $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$, was ground up with the pentahydrate, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, and sealed up in a glass tube. A sample of Rochelle salt was treated in a similar manner after adding 5% of the anhydrous compound. Only slight agglomeration occurred in both cases, and this was attributed to the changes produced by grinding, and to unequal distribution of the lower hydrate or anhydrous salt. In order to eliminate these secondary causes of caking fully hydrated samples of both salts were prepared in the form of tiny crystals, which were then subjected to 2% dehydration with stirring, and packed as before. The effect of this treatment was to disintegrate the surfaces of the crystals and to coat them with a film of lower hydrate; as a result, there was not the slightest tendency to agglomeration after a period of several months.

These results suggested the possibility of preventing the caking and contraction of other substances, crystallising without water of crystallisation, by the addition of a small percentage of the anhydrous form of some salt capable of forming a definite crystalline hydrate. A series of experiments was made in each of which 40 grms. of dry ammonium nitrate was taken from the same sample, 1% of water added, and then 1% of a dehydrated salt. Each mixture was stirred, transferred to a hard glass tube, closed by a tightly fitting rubber stopper, and sealed with collodion. A sample of ammonium nitrate with 1% water but no anhydrous salt was prepared at the same time and packed under the

same conditions. The tubes were set aside for a month, when the following observations were made:

SUBSTANCE USED.	RESULT.
Water only	Decided caking, large contraction
Anhydrous calcium chloride.	Caking with contraction.
Anhydrous magnesium sulphate.	Do. Do.
Dehydrated alum.	Slight caking, no contraction.
Anhydrous copper sulphate.	Do. Do.

The different effects produced by the various anhydrous compounds are probably due to differences in the stability of the hydrates to which they give rise. All the samples were, of course, subject to variations of temperature. In order to test the behaviour of samples containing a smaller proportion of water, 2% of anhydrous copper sulphate and 2% of fused calcium chloride were added in two experiments to ammonium nitrate containing only 0.1% moisture. After two months the particles were still perfectly free.

These experiments show that it is possible to prevent the caking of crystalline salts by this method, but the relatively large amount of foreign material that is required makes the method impracticable for industrial purposes.

Two insoluble salts, barium sulphate and calcium carbonate (2½%), when added to ammonium nitrate (1% moisture), at first appeared to prevent caking, but subsequently a gradual hardening took place, which was attributed to chemical interaction.

19. EFFECT OF COLLOIDS.

It was thought that, since the changes under consideration were produced by crystallisation, it might be possible to inhibit them by the addition of a colloid. Agar-agar, powdered gum arabic, gelatin and glue were the colloids used, but here again the amount necessary to produce a change worthy of consideration makes the adoption of such a method of theoretical interest only. Agar-agar seemed to have the most marked effect; a sample of ammonium nitrate containing 0.2% of water and 2% of agar showed no tendency to agglomerate. A sample of ammonium nitrate crystallised from a solution containing 1% of gum arabic produced crystals which showed none of the needle-like structure so characteristic of this salt.

20. RECOMMENDATIONS.

From the experiments and observations that have been described in this paper, and the conclusions that have been drawn therefrom, it will be seen that caking is most likely to take place:—

- (a) In crystalline salts that are very soluble.
- (b) In hygroscopic and deliquescent substances.
- (c) In crystalline hydrates.
- (d) In substances that are liable to decompose in the presence of moisture.

In order to minimise the troubles that are caused by caking the following measures are suggested:—

(1) Care should be taken to reduce to a minimum the number and amount of soluble impurities.

(2) When substances are handled in bulk and are not required in a very pure condition, the most convenient method of supply is in the form of large crystals, the surfaces of which have been dried, e.g., in a centrifugal machine, without breaking up the crystalline structure. The larger the crystals the fewer will be the points of contact between them and the smaller will be the tendency for the material to bind together.

(3) When a finer product is required, the most satisfactory way of supplying it is in minute unground crystals, e.g., as prepared by the rapid cooling of a saturated solution with constant stirring whilst crystallisation is in progress. The surfaces of these crystals should be dried before packing. The method of drying will depend on the nature of the substance, but agitation during drying is a very

important factor. In the case of hydrated salts the surfaces of the crystal should be slightly dehydrated.

(4) When a substance is specially required in a finely-powdered form, there should be careful drying, with agitation, after grinding. This is a very important point which has often been neglected. Great care has been taken to dry the crystals before grinding, but the fact that moisture is released by grinding and needs to be driven off subsequently does not appear to be generally recognised in commercial practice. This measure applies particularly to hydrated salts.

(5) As far as possible the drying should be carried out at low temperatures; or, if the first part of the drying is conducted at higher temperatures, the finishing process should be at atmospheric temperatures.

(6) Substances should not be packed hot unless all traces of moisture have been removed.

(7) Steps should be taken to maintain a "dry" atmosphere during packing. In order to prevent absorption of moisture, the pressure of aqueous vapour in the atmosphere should be less than the vapour-pressure of a saturated solution of the salt. This can be checked by taking care that the difference between the readings of the wet and dry bulb thermometer does not fall below a fixed minimum depending on the hygroscopicity of the salt. This difference can readily be maintained in winter by working in a warm room, but this method of drying the air is open to objection in summer.

(8) Care should be taken to prevent access of moisture to the substance after packing, e.g., by taking care that it is packed in a dry vessel; this applies particularly to wooden boxes, casks, etc.

(9) When substances that are particularly liable to cake in the presence of moisture are packed in glass bottles, the corks should be covered with paraffin wax or some similar waterproofing material. When tins are used the edges of the lids, if not soldered, should be bound by adhesive tape. Casks may be lined with paraffined paper to check the access of moisture to the contents.

(10) Caking may be minimised by keeping the temperature as constant as possible during storage.

21. SUMMARY.

The caking of salts is in general dependent on the presence of a solvent, usually water. The following cases have been studied:—

(1) *Nitrates*.—In the case of ammonium nitrate very hard caking follows the change of state which takes place at 32° C., but this caking can be prevented by very thorough drying. Hard caking also follows upon mechanical disintegration of the warm salt, but this is also attributed to the influence of moisture released during disintegration. Ammonium nitrate crystallised from alcohol shows much less tendency to cake than when crystallised from water. Caking of ammonium nitrate due to mechanical working is only slight when the conditions are such that moisture can escape from the powder.

Sodium nitrate forms a very hard cake when stored in bulk, but this can be prevented by commercial drying, whereas it is precisely this process which gives rise to the most serious caking in ammonium nitrate. This difference is attributed to the polymorphism of ammonium nitrate, which has no analogy in the case of sodium nitrate.

Potassium nitrate, which is less soluble than either of the two preceding salts, may cake during storage, but apparently to a much smaller extent.

(2) *Other anhydrous compounds*.—Serious caking is reported to occur, not only in common salt and in soda ash, but also in potassium chlorate, potassium perchlorate, citric acid, and tartaric acid. In the last four cases caking frequently accompanies or follows the grinding of the dried crystals. This is

probably due to the liberation of more moisture during grinding, and can be prevented by drying the compound during or after grinding, and packing in a dry condition.

(3) *Hydrated salts*.—Caking of hydrated salts frequently gives rise to trouble, e.g., in the case of Rochelle salt, borax, sodium phosphate, and alum. These hydrates cannot be dealt with in the same way as anhydrous salts, since it is difficult to secure complete drying of the hydrate without partial decomposition. The view is advanced that mechanical working of a hydrated salt not merely releases included moisture, but may result in a breaking up of the hydrate similar to that which takes place when the salt is heated, just as the phenomena which accompany the formation of amorphous materials during cold-working may be compared with the effects produced by fusion. Grinding is found to be accompanied by a slight loss in weight, which is recovered very quickly from the air. It is not thought that this is sufficient to account for caking of the salt, which is attributed rather to recrystallisation following on the disturbance of the normal distribution of water which results from the grinding of the salt, just as sodium sulphate may recrystallise in the normal form after being melted in its water of crystallisation.

(4) *Loss of sulphur dioxide during caking*.—Sodium bisulphite and sodium hydrosulphite cake on exposure to air, but this is a more complex change, since not only is water absorbed, but sulphur dioxide is also liberated.

(5) *Contraction during caking of copper sulphate*.—When powdered anhydrous copper sulphate is exposed to moist air it swells considerably during hydration, but the absorption of the final 1 per cent. of water is accompanied both by caking and by strong contraction. The slight excess of water taken up by the blocks is quickly lost in a dry atmosphere when hydration and caking are complete. Caking and contraction in this case are believed to be due to the simultaneous presence of particles of the trihydrate and of water saturated with the pentahydrate, in which the trihydrate dissolves and crystallises out again in the ordinary form. The caking of hydrated salts can be prevented by the presence of a small amount of a lower hydrate, which absorbs the traces of moisture which are so effective in producing caking in a salt which is almost fully hydrated.

Attention is directed to the disintegration which accompanies the change of state of ammonium nitrate when dried by heat and which is also observed in the dehydration of many hydrated salts. This disintegration may be used as a substitute for grinding, just as in the converse process of slaking lime by the addition of water.

DISCUSSION.

Dr. J. A. HARKER said that three years ago, after many preliminary experiments in conjunction with some members of the staff of the Ministry of Munitions Research Laboratory, it had been found that under proper conditions it was possible to produce solid ammonium nitrate, free from nitrite, directly by interaction of ammonia, steam and air, with excess of oxides of nitrogen obtained from the oxidation of ammonia. That promised to be an important process, possibly of commercial value. Ammonium nitrate made in that way was nothing like so deliquescent as ordinary ammonium nitrate. It took up water, at all events initially, at a very different rate. If a bottle full of fresh crystals were left to stand for 24 hours, the crystals would be found to have sunk down by about 20 per cent. in volume, but nothing more happened, and if kept dry it remained in the form of fine microscopic crystals, without any visible tendency to cake, even after long keeping.

Mr. A. E. BERRY asked the author if he had ascertained what methods were used by the manufacturers of table salt who had, he believed, solved the problem of caking. He concurred in the view of the author that caking was entirely due to moisture. If an anhydrous salt were ground and re-dried, the problem of caking was solved. If the drying of chemicals was hastened, or if the temperature was too high, caking was bound to occur. It was possible to dry sodium phosphate and grind it into powder containing as much as 30 per cent. of moisture and it would not cake, yet if dried under different conditions it might cake with only 10—15 per cent. of moisture.

Sir ROBERT ROBERTSON thought the author had made out a strong case for the dominant influence of moisture in regard to caking, particularly in connection with ammonium nitrate. The question of the formation of pellets was more or less analogous to the phenomenon of caking. While, on the one hand, ammonium nitrate when perfectly dry, or with a moisture content of about 0.020%, would form into pellets having a definite cohesion with a certain pressure, less pressure was required to get the same cohesion with ammonium nitrate containing about 2 per cent. of moisture. But while ammonium nitrate was thus in line, there were other substances which did not appear to be so. Calcium carbonate gave coherent pellets with varying proportions of moisture, but calcite, under similar circumstances, gave a very friable pellet, the particles in this case seeming to retain their original crystalline form and prevent cohesion. Barium sulphate was like calcite in giving friable pellets, and the hardness of the substance appeared to be of importance. There was undoubtedly much work to be done yet on the conditions favouring the formation of coherent pellets.

Dr. S. RIDEAL recalled that during the Boer war pellets of sodium bisulphate had been required to sterilise water from typhoid; the machine had to be lubricated with boric acid to prevent caking of the salt. The pellets became so hard on keeping that they could not be dissolved in water; this difficulty was overcome by adding a little sodium carbonate to the bisulphate.

Dr. H. BORNS asked if copper sulphate changed colour at any definite stage of hydration.

CAPTAIN C. J. GOODWIN suggested that the impurities in the material might be of some importance in regard to caking. He believed that one of the chief impurities which promoted caking of table salt was calcium sulphate, whereas to prevent deliquescence of sodium nitrate it was necessary to remove the sodium chloride.

Mr. J. G. A. RHODIN did not think that hydration had so much to do with caking of salts as the author seemed to think. The principal factor, it seemed to him, was that adhesion turned into cohesion between the crystals. During the past fortnight he had had the experience of using ordinary Portland cement as the hearth for smelting metal at high temperature. Cement was believed to hold together on account of hydration by adhesion of water, but he had found recently that Portland cement when used as the hearth for smelting metal at 1200° C. held together after a fortnight. He mentioned the well-known case of the adhesion of metal surfaces when placed in contact. The difficulties with ammonium nitrate could be overcome by proper drying.

Dr. R. LESSING asked if the ammonium nitrate used and also the products at the various temperatures of transition were perfectly neutral. It had been found practically impossible to dry ammonium sulphate unless it was at the same time neutralised;

to obtain a salt which would remain perfectly dry and in a fine condition, it was necessary to grind it at the time of drying. This agreed with Dr. Lowry's suggestion that more moisture could be extracted from the inside of the crystals, after the crystals had been once broken up, than from the surface. Whilst agreeing with Dr. Lowry's explanation, he suggested that at the high temperature of 70° C. a certain amount of dissociation might take place, and that nitric acid was formed as well as free ammonia. If that were so, it would be possible that on re-combining the fragments of the dissociated molecules did not re-combine exactly with each other, and that this facilitated caking in a measure that water alone would not justify. This would also explain why caking took place so suddenly after drying. In all the cases described the drying was not very perfect, and that again would account for the rearrangement of acid and ammonia in some of the water. The solubility of ammonia gas in solid ammonium nitrate, investigated by Divers, proved that this salt stood in a class by itself. The acidity of ammonium sulphate was almost invariably due to pyridine in the form of bisulphate, which could never be got entirely neutral without loss of pyridine; if pyridine were present in the original gas liquor from which the sulphate had been made, the neutralisation would never be complete until the whole of the pyridine had been driven off and the acid set free by that method neutralised again.

Mr. R. G. EARLY gave some figures to illustrate the pressure necessary to produce coherent pellets with certain salts. The figures were obtained by pressing the salt at known pressures until a coherent block was obtained as tested by the "Autopunch" on the principle of the Brinell hardness test. In the case of ordinary soluble salts the pressure necessary to give coherence was:—Ammonium chloride, 0.4 ton per sq. in.; potassium nitrate, 0.75 ton; ammonium sulphate and common salt, 1 ton; sodium nitrate, 1.3 ton; potash alum, 2 tons. In the case of insoluble salts, precipitated calcium carbonate required 0.8 ton; the same material after six hours in a steam oven at 100° C. required the same pressure; calcite in the form of small crystals, 20- to 30-mesh, did not very easily go into the form of pellets, and after pressing at 4 tons it could be easily broken down; calcite ground down to 60-mesh showed the same characteristics, as it also did after six days' exposure to the air. Barium sulphate did not produce a coherent block with 8 tons pressure, but broke down into laminae with a gentle pressure of the fingers. Analysing these results, it was seen that in the case of soluble salts, solubilities and pressures did not run parallel, though there was an indication that the less soluble were the more easily pressed into coherent blocks. Ammonium nitrate, however, took a place among the more insoluble salts, an average sample requiring a very small pressure, comparable with that for ammonium chloride. Considering the behaviour of insoluble salts, barium sulphate showed extreme reluctance to bind together. Fineness of material did not appear to have any great effect, there being, perhaps, a little greater difficulty in pressing the finer material. With regard to the amount of mother liquid required for pressing to coherence, ammonium nitrate under a pressure of 0.5 ton went into coherent pellets with 2% of water present; small crystals containing 0.15% required 0.4 ton. When drying was resorted to the results were as follows:—0.16% moisture, 0.45 ton; 0.10%, 0.5 ton; 0.07%, 0.6 ton; and very fine powder containing less than 0.05% moisture, 0.8 ton. Although the effect of drying was not very marked, there was a distinct tendency for the pressure to increase as the salt became more completely dried. The time of pressing was very short, and practically no

time was allowed for maturing, such as was the case when ordinary setting took place. Whilst the actual effect of pressure was to increase the solubility in most cases, ammonium chloride was the well-known exception, and would be deposited from solution under pressure.

PROF. PORTER said that the direct effect of pressure could only be ascertained definitely if pellet formation were conducted at various temperatures. If, for example, some chemical change took place under pressure, he thought it would be found that there was rather a great rate of change with temperature. On the other hand, if it was purely a physical change that was brought about—the mere effect of bringing particles into closer proximity and bringing molecular forces into play—then the pressure required would vary very little with temperature, and would probably diminish as the temperature rose. The influence of pressure upon solubility could be of two kinds. In the first place, supposing a material system which was throughout under pressure, there would be a slight variation of solubility applying to that case. On the other hand, a second case could arise, and judging from Dr. Lowry's remarks he fancied that this was probably the one which came into practice, and that was the case in which the whole of the system was not throughout under the same pressure; in which the liquid into which the solid was dissolving was not under pressure, but might be escaping at the edge, and therefore the pressure was removed. In that case there were precisely analogous phenomena to the solidification of water into ice. With ice and water both under pressure, the variation of the melting point with pressure was $1/140^\circ$ for each atmosphere increase, assuming that the solid ice and the water were both sustaining a pressure of 140 atm., but when the water was escaping freely from the region under pressure the lowering of the melting point was 10 or 11 times as great. That might have a very important bearing upon the problem of the alteration of solubility with pressure which Dr. Lowry brought in to account for the solution taking place which was followed by crystallisation at a subsequent stage. In such a case the actual variation of solubility with pressure might be expected to be very much larger than it would otherwise be. There were many other problems which had to be brought under consideration, and particularly the problem of the effect of complete dryness.

DR. LOWRY, in replying, said that he assumed that pure sodium chloride, in saturated solution, did not give a sufficiently low vapour pressure to absorb moisture from an atmosphere containing an average amount of moisture. The presence of impurities lowered the vapour pressure to a point at which moisture was either absorbed or lost from day to day, and this was really the dominant factor there. With regard to copper sulphate, he did not think there was any change of colour during the caking and shrinkage, as the salt was already almost fully hydrated. The question had been raised as to whether the caking of ammonium nitrate might not be due to the dissociation into ammonia and nitric acid, and whether the ammonium nitrate used was neutral. As a matter of fact, it was; the English ammonium nitrate was always boiled down in alkaline solutions containing free ammonia, and that was why it was always free from pyridine; the American ammonium nitrate was evaporated in acid solution, and they had the pyridine as an impurity whilst we had thiocyanates. He was convinced that moisture was not the universal cause of caking, and that when dealing with substances other than salts other causes operated, e.g., he was an entire believer in the theory of amorphous materials, and in the consolidation of metals by cold welding or by flow through an orifice

it was pretty certain that these were the operative causes. He had wanted to attribute the caking of salts to causes which might be universally operative, but when he had been shown ammonium nitrate which did not cake merely because it had been dried, he felt bound to admit that moisture was the fundamental cause of caking in this salt.

Dr. T. MARTIN LOWRY and Mr. S. WILDING presented a note on the setting of dental cements, as follows:—

The most important cases of caking or setting may be classified as follows:—

1. *Recrystallisation of an anhydrous or hydrated salt without change of chemical composition, as discussed in the preceding paper.*

2. *Formation of hydrates, as in the setting of plaster of Paris, although in this case the hydration is followed by a recrystallisation without change of composition:*

3. *Hydrolysis of complex salts by water, as in the setting of barium silicate as formulated by Desch, $\text{Ba}_2\text{SiO}_4 + 15\text{H}_2\text{O} = \text{BaSiO}_3 \cdot 6\text{H}_2\text{O} + \text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$, and of Portland cement.*

4. *Formation of new salts, e.g.:—*

(a) *Magnesium oxy-chloride cements, in which a basic chloride is formed by the addition of aqueous magnesium chloride to powdered magnesium oxide,*

(b) *Zinc oxy-phosphate cements, used very largely in dentistry, in which zinc oxide is converted into a basic phosphate by a solution of phosphoric acid which may already contain some zinc phosphate.*

(c) *"Silicate" cements, in which various silicates, and various salts of aluminium, are converted into phosphates by the action of an aqueous solution of phosphoric acid, sometimes saturated with aluminium or zinc phosphate.*

(d) *Caking, practically equivalent to the formation of a cement, accompanies the conversion of calcium phosphate by the action of sulphuric acid into a mixture of sulphate and superphosphate.*

5. *Amalgams.*—In these cements mercury takes the place of water. Unfortunately no information appears to be available in reference to the setting of the amalgams of copper and palladium, which have both been used effectively in dentistry, but cadmium amalgam appears to set because the solid solution of mercury and cadmium, which is isomorphous with mercury, is less soluble at atmospheric temperatures than a corresponding solid solution isomorphous with cadmium.

The best of the amalgam-cements is, however, made by the action of mercury on an alloy of silver and tin. Experiments carried out in the laboratories of Professor McBain at Bristol have proved that the setting of this amalgam is due to the chemical change shown in the equation,

The more complex cases of setting, which are set out under the last two headings, are used very extensively in dentistry, where the conditions are particularly exacting and the cost is of little importance, in view of the small quantities used. They are well worthy of detailed study in any scheme for the elucidation of the general phenomena of caking or setting. Thus, one point demanding investigation is the part played in all these changes by amorphous or colloidal material, which appears to be important even in the case of the amalgams.

Bristol and S. Wales Section.

Meeting held at Cardiff on March 3, 1920.

MR. W. S. HIRD IN THE CHAIR.

RESEARCHES ON COAL.

Part I.—The thermal decomposition of coal at low temperatures.

BY S. ROY ILLINGWORTH, B.Sc., F.I.C., A.R.C.S.

The thermal decomposition of coal at low temperatures has been investigated by a number of independent workers, both as regards the gaseous products evolved at definite temperatures, and as to the liquid products. Important results have been published by Burgess and Wheeler (Trans. Chem. Soc., 1910—1914), Porter and Ovitiz (U.S. Bureau of Mines), Porter and Taylor (U.S. Bureau of Mines), Jones and Wheeler (Trans. Chem. Soc., 1915), and others, and a study of certain Scotch coking coals was carried out by Anderson in 1895. An excellent and critical survey of the subject is contained in the monograph on the "Constitution of Coal" by Stopes and Wheeler, pp. 7-12 (H.M. Stationery Office).

The present communication deals with the results of an investigation planned to elucidate the relative stability of certain known components of coal when subjected to carbonisation under standard conditions. The relative behaviour of certain coals when carbonised at various temperatures up to 450° C. has been studied. The coals chosen are coals which when carbonised at 950° C. yield cokes of different types. The samples used were "mine" samples, cut from roof to floor of the seam, and they comprised about 80—100 lb. of coal, from which a 14 lb. laboratory sample was obtained by the usual process of quartering down the bulk; this smaller sample furnished the coal actually used in the investigation.

The analyses of the coals were as under:—

TABLE I.

	No. 2 Llantwit.	No. 3 Rhondda, S. crop.	No. 2 Rhondda,	Two-foot nine, S. crop.

S	2.08	0.64	1.95	0.63
Ratio C/H	14.29	17.34	20.22	17.75

The No. 2 Llantwit is used for gas making and yields a very porous coke. On the basis of the classification of coals as revised by Professor Bone (see "Coal and Its Uses," p. 64), it must be classed as a "caking long-flame coal of the bituminous genus."

The No. 3 Rhondda is carbonised to produce metallurgical coke and is also used in the gas industry. The coal yields a dense coke which tends to be brittle. This coal is classified as a "hard coking, bituminous coal," and is intermediate between the gas coals and the typical coking coals. The Two-foot-nine is a typical "hard coking coal," whilst the No. 2 Rhondda is a "hard coking (short-flame) coal" and yields a dense coke.

A known weight of the coal ground to the same degree of fineness was submitted to the influence of definite fixed temperatures for varying periods of time and the resultant loss of weight determined. Since the liquid products were not completely volatile at the temperatures maintained in the work, the residue from each heating operation was washed with cold carbon tetrachloride to remove the oily substances, dried *in vacuo* at 105° C., and then weighed. The loss of weight was calculated on the washed and dried residue. A known weight of the final residue was extracted with pyridine in a Soxhlet apparatus and the pyridine extract dried and extracted with chloroform. This cycle of operations furnished the data necessary for calculating the amounts of the pyridine-soluble compounds, the γ - or resinic bodies, and the β -cellulosic substances in the residues at different stages. The terms β - and γ -compound are used in conformity with the terminology proposed by Wheeler. The β -compound is that portion of the coal soluble in pyridine but insoluble in chloroform, whilst the γ -compound is that portion soluble in both pyridine and chloroform. The processes outlined above were carried out as follows:—

Drying.—All coals, extracts, or residues were dried in a vacuum oven at 105° C., under a pressure of 60 mm. of mercury.

Heating the coals.—The samples of coal were ground to pass through a 30-mesh sieve and to be retained on a 60-mesh; 25 grms. of dry coal was used for each charge, and was heated in an electric muffle 2 in. \times 4 in. \times 10 in. The heating tubes were made of 1-inch Mannesmann tubing so arranged that 10 in. of the tube was in the oven. The tubes were charged with coal, exhausted, filled with dry nitrogen, and the open end of the delivery tube closed by a rubber cap. They were inserted in the oven when a steady condition of temperature in the muffle had been attained, as indicated by no fluctuation greater than 5° C. being recorded in an hour, and the delivery tube was immediately connected to a vessel containing nitrogen. The time requisite for the whole charge to reach the temperature of the oven was found to be 30 mins. when the oven was stabilised at 450° C., 40 mins. at 400° C., and 45 mins. at 350° C. The tubes were heated one by one, and throughout the period the variation of the temperature of the oven did not exceed $\pm 5^\circ$ C. At the end of the experiment the exit tube of the charged tube was attached to a nitrogen supply, the heating tube was withdrawn from the furnace, and cooled by gradually lowering it into water. The residue was rapidly weighed, placed in a flask, and covered with carbon tetrachloride. The flask was shaken for three or four minutes, allowed to stand for one hour, the mixture filtered, the residue washed with carbon tetrachloride, dried *in vacuo* for two hours, and weighed. Repeat determinations of the loss of weight of a coal under definite conditions agreed within 0.2%.

Pyridine extractions.—The portion of the coal or residue which passed an 80-mesh sieve but was retained on a 90-mesh sieve was dried *in vacuo* for one hour; 5 grms. was mixed with 5 grms. of ignited sodium chloride, and the mixture extracted in a dry double-walled extraction thimble in an atmosphere of nitrogen, in a Soxhlet apparatus, the end of the condenser being connected with a manometer tube. The temperature was so regulated that the siphon functioned every 12 minutes. The pyridine used distilled entirely between the limits 116° C. and 122° C., and was prepared from the commercial product by fractional distillation and drying over caustic potash. The extraction was conducted with 250 c.c. of pyridine as follows:—The apparatus was kept continuously at work for 120 hours, then allowed to cool, and a fresh charge of pyridine

placed in the flask. The charge in the thimble was well stirred and the apparatus re-charged with nitrogen, after which the extraction was continued for a further 72 hours. The charge in the thimble was again mixed, and after re-filling with nitrogen the apparatus was kept at work for a final period of 48 hours. The united pyridine extracts were concentrated to a convenient bulk in an atmosphere of carbon dioxide, and the cold residue was slowly poured into an excess of 1:1 hydrochloric acid made with air-free water, the precipitate filtered, washed until it was free from acid, dried for eight hours *in vacuo*, and weighed.

A definite weight of the dried extract was extracted on the water-bath with pure dry chloroform in a similar apparatus; in this case the extractions were continued for at least one day from the time the chloroform in the extraction chamber had become colourless—a stage generally reached about 48 hours from the commencement of the process. The chloroform solution was filtered through a tared paper and the weight of any β -cellulose mechanically carried over during the extraction was added to that determined by weighing the contents of the thimble after it had been dried *in vacuo* for 2 hours. The amount of β -cellulose present in any coal or residue is based on the direct weight obtained by the above method. The resinic matter was determined by distilling off the chloroform in a tared flask and weighing the residue, but the results for resin are taken as the difference between the amounts of pyridine-soluble and the amount of β -cellulose. The investigation necessitated the preparation of comparatively large amounts of the β -cellulosic and resinic substances. These were prepared by extracting in an atmosphere of nitrogen a definite amount of coal contained in a metal flask which was heated on an air bath and the pyridine extract was subsequently extracted with chloroform in a Soxhlet apparatus.

Volatile matter was determined by heating 1 grm. of coal etc. in a platinum crucible for seven minutes in an electric muffle maintained at the temperature specified.

Sulphur was determined by the Eschka method.

Nitrogen was determined by the modified Gronig Kjeldhal method. The ammonia was distilled into 10 c.c. of standard acid, the excess of which was determined by titration with *N*/10 ammonia solution, using cochineal as indicator.

Method of calculation.—All results, unless otherwise specified, are calculated to an ash-free and dry basis. Such figures are subsequently referred to as based on the "coal substance."

Pyridine extraction of the original coal.—In the course of the study of the behaviour of the coals

vals of heating. In nearly every case an enhanced amount of the coal substance was soluble in pyridine, a result in agreement with the observations of Harger (this J., 1914, 389, 393). Since it was found necessary to maintain the charge of coal for half an hour at a temperature of 450° C. before the charge was in thermal equilibrium with its surroundings, the rate of the decomposition of the coal substance was based upon the residue resulting from placing the heating tube for half an hour in the muffle regulated to maintain a constant temperature of 450° C. During this period the temperature of the muffle fell to 370° and then gradually rose to 450° C., which temperature was reached 25 mins. after the insertion of the tube. The amounts of the various substances present in the residues thus obtained are given in Table II.

The amounts of the constituents determined by direct extraction of the virgin coal are given in Table III., from which it is evident that the enhanced values of the pyridine-soluble figure is greater in the case of the true coking coals.

The different properties of these coals are due rather to the nature of their various constituents than to the quantity present. Further work on the nature of the constituents is proceeding. Meanwhile the following characteristics reveal marked differences in the constituents from the different coals.

at 450° C. anomalous results were obtained for the amount of substance extracted by pyridine from the residues obtained after comparatively short inter-

The above analyses reveal the same gradation in nature of the constituents as exists amongst the coals, and again indicate that No. 3 Rhondda is

intermediate in nature between the gas-making coals and the true coking coals, but no generalisations as to the various factors determining the coking qualities are evident from a survey of these figures.

An endeavour was made to elucidate the causes of the variation of the nature of the coke produced by

particles comprising the cokes had very rounded edges. The whole of the various charges of the No. 2 Rhondda were easily poured from the tubes and the particles of the residue were possessed of sharp unaltered edges—a fact which leads one to believe that no softening of the coal had taken place at this temperature.

these coals by investigating the thermal stability of the components. Considerable differences in the stability of the coals were shown by the behaviour at 350°, 400°, and 450° C. for varying intervals of time. The results for the percentage loss of weight under varying conditions are given in tables V., VI., and VII.

TABLE V.
Loss of weight of coal substance at 350° C.

Coal.	Hours of heating.*			
	1½	2½	4½	10½
No. 2 Llantwit	0%	0%	0%	0.94
No. 3 Rhondda	2.14	2.21	3.66	5.94
No. 2 Rhondda	0.85	1.25	—	2.27
No. 2 Rhondda	0.91	1.34	2.00	2.43

* From insertion of tube into oven stabilised at 350° C.

In every case the whole of the residue was readily emptied out of the tube, it exhibited no sign of cohesion, and the edges of the individual particles were as sharp as those of the original charge. These facts preclude the idea that the residue had melted or softened. Anderson gave 300° C. as the softening point of the Scotch coking coals which he examined, whereas the above coals do not soften or coke at 350° C. The above figures show that the No. 2 Llantwit is the least stable of the coals examined, and that the other two are of the same order of stability at this temperature.

TABLE VI.
Loss of weight of coal substance at 400° C.

Coal.	Hours of heating				Remarks.
	1½	2½	4½	10½	
No. 2 Llantwit	5.93	7.73	9.52	12.77	Residue had all coked.
No. 3 Rhondda	2.6	3.73	4.26	8.43	
No. 2 Rhondda	2.15	2.54	3.61	4.77	No residue had coked.

No. 2 Llantwit thus decomposes progressively at 400° C. to a very considerable extent, No. 3 Rhondda more slowly (by comparison), and No. 2 Rhondda only very slowly. This may represent the decomposition of certain constituents unstable at 400° C. which are present in different amounts in the three coals. The cokes from the first two coals were very brittle and possessed a very bright appearance—one might term them "Coal bright." The individual

These figures reveal the rapid initial decomposition of the coals at 450° C. and the greater volatility of the first two coals compared with the coking coals. The dense coking coals approach their maximum volatile figure at this temperature in a comparatively short time, whilst the other two coals approach it more gradually. The residues were coked in every case with the exception of that residue resulting from the half-hour treatment of the No. 2 Rhondda; this had cohered into lumps in various places, and there were definite signs that an incipient softening of the coal had taken place.

From the above results around 400° C. may be taken as the temperature of coke formation for the porous coking coals, and 430°—450° C. for the dense coking coals. In view of these results the thermal behaviour of the β -cellulosic and resinic constituents in the coals was investigated at 450° C.

Relative stability of β -cellulosic and resinic constituents.—No. 2 Rhondda.

TABLE VIII.
Constituents in residues from coal at 450° C.

Period, hrs.	In residue.			In residue ex 100 coal substance.		
	Pyridine soluble.	β -Cellu-losic.	Resinic.	Pyridine soluble.	β -Cellu-losic.	Resinic.
1	26.66	16.48	10.18	28.41	17.56	10.85
1½	21.33	13.34	7.99	22.04	13.79	8.25
2	9.23	4.22	5.01	9.18	4.19	4.99
5½	4.10	0.98	3.12	4.04	0.96	3.08
12½	3.2	0.6	2.6	3.14	0.58	2.56
24½	1.9	nil	1.90	2.10	nil	2.10

The rapid decrease in the amount of substance soluble in pyridine is thus due in a greater degree to the destruction of the β -cellulosic than to the destruction of resinic substance. The relative ease of decomposition of the several constituents is more clearly indicated in the graphs in Fig. 1, which have been arrived at by subtracting from the half-hour values the amounts of any constituent present at the end of a particular period of heating, and expressing this difference as a percentage of the amount present in the half-hour residue.

The curves for both the β -cellulose and resinic constituents tend to exhibit a point of flexure at the end of the 5-hour period, no doubt due to the presence of two types of compound in each of these constituents—one readily decomposed at 450° C., and the other more stable. The fact that the point of flexure in the curve for the β -cellulose occurs when more than 90% of this constituent has been decomposed suggests that this

type of constituent in the No. 2 Rhondda approximates to a homogeneous substance. An alternative explanation of the point of flexure is that the slower rate of change of these compounds in the later periods is due to the decomposition of secondary products still soluble in pyridine which arise from the destruction of the primary substance.

Fig. 1.

Analyses of several of the β -cellulosic and resinic components isolated from various residues are given in Table IX.

H	4.95	4.89	6.31	5.95
Ratio, C/H ..	16.92	17.09	13.66	14.91

These figures confirm the homogeneity of the β -cellulosic constituents in so much as no great difference is produced by partial destruction. The resinic substances appear to be less homogeneous than the β -cellulosic constituents; the more stable resinic has a greater C/H ratio than the resinic less stable at this temperature.

In so much as the β -cellulosic substances decompose more rapidly than the resinic bodies, the ratio of the resinic to β -cellulosic substance must increase as decomposition of the coal proceeds.

Nitrogen and sulphur.

The nitrogen and sulphur were estimated in the various residues, and the amounts present in the residues from one hundred parts of the coal substance were calculated from the figures thus obtained. Details of the results are given in Table X.

TABLE X.

Nitrogen and sulphur in residues ex 100 grms. coal substance.—No. 2 Rhondda, 450° C.

Hours of heating.				N. %	S. %
Original coal	1.42	1.95
1½	1.38	1.99
2½	1.25	1.90
5½	1.21	1.79
12½	1.23	1.57
24½	1.25	1.61

The decomposition at 450° C. of the nitrogenous substance in the coal thus results in the elimination of approximately 15% of the total nitrogen in the

coal. The nitrogenous substance decomposed is markedly unstable at this temperature, the decomposition being completed in the first two hours. The subsequent figures agree within the limits of experimental error. The continuous elimination of sulphur over the first period of twelve hours indicates the gradual decomposition of sulphur compounds moderately stable at 450° C.

TABLE XI.

Two Foot Nine seam. Constituents in residues at 450° C.

Period, hrs.	Percentage to residue.			Amount in residues ex 100 coal substance.		
	Pyridine-soluble.	β -Cellulosic.	Resinic.	Pyridine-soluble.	β -Cellulosic.	Resinic.
$\frac{1}{2}$	31.94	20.04	11.90	31.99	20.07	11.92
1½	18.40	9.78	8.62	17.36	9.22	8.14
2½	13.68	7.32	6.36	12.47	6.51	5.79
5½	7.43	2.92	4.51	6.72	2.64	4.08
24½	1.12	nil	1.12	1.01	nil	1.01

The curves drawn from these figures are generally similar to those obtained from the figures of Table VIII.

The percentage loss of the various constituents with lapse of time have been calculated as for fig. 1, and are plotted in fig. 2.

Fig. 2.

These curves emphasise the slower initial decomposition of the various constituents of this coal compared to the No. 2 Rhondda. The apparent homogeneity of the β -cellulosic constituent is indicated, but is not quite so pronounced as in the case of the No. 2 Rhondda. These coals exhibit a close similarity in their behaviour and mode of decomposition at 450° C. Analyses of various constituents isolated from several of the residues are given in Table XII.

TABLE XII.

	β -Cellulosic.		Resinic.	
	1½ hours residue 450° C.	5½ hours residue 450° C.	1½ hours residue 450° C.	$\frac{1}{2}$ hour residue.
C	83.08	82.85	87.80	85.76
H	4.72	4.19	6.43	6.53
Ratio, C/H ..	17.60	19.77	13.67	13.13

The homogeneity of the β -cellulosic constituent is not so clearly indicated by these results.

Nitrogen and sulphur.

The amounts of nitrogen and sulphur in the residues calculated on the basis of the residue arising from 100 parts of coal substance are detailed in Table XIII.

TABLE XIII.

Nitrogen and sulphur in residues ex 100 grms. coal substance.

Two Foot Nine. Temperature 450° C.

Hours of heating.				Nitrogen in residue.	Sulphur in residue.
Original coal	1.34	0.63
1½ hours	1.34	0.63
3½	1.26	0.63
5½	1.29	0.69
12½	1.31	0.67
24½	1.34	0.60

It is evident that in the case of this coal the early stages of decomposition are not associated with the destruction of molecules containing nitrogen or sulphur to any appreciable extent.

No. 3 Rhondda S. crop.

TABLE XIV.

Percentage of constituents in residues obtained at 450° C.

Hours of heating	Percentage in residue.			Amount in residue ex 100 coal substance.		
	Pyridine-soluble.	β -Cellulose.	Residue.	Pyridine-soluble.	β -Cellulose.	Residue.
1½	31.22	19.03	11.20	30.98	19.77	11.21
2½	28.20	18.34	9.86	26.34	17.14	9.20
3½	26.62	16.29	10.32	24.60	15.03	9.57
5½	19.66	11.43	7.58	17.66	10.27	7.39
9½	18.36	10.78	5.30	16.33	9.61	6.72
24½	12.14	6.41	5.73	10.37	5.48	4.89

These results show that β -cellulose is associated with the resinic substances throughout the period of heating, and that the decrease in the amount of these substances present with the variation in the time of heating is far less rapid than is the case in the other two coals considered.

The percentage losses of the constituents with variation in the duration of heating, calculated as before, are plotted in Fig. 3.

Fig. 3.

It is evident that the pyridine-soluble constituents of this coal are more stable than the corresponding substances in the Two Foot Nine and No. 2 Rhondda, for in the latter coals approximately 95% of the

pyridine-soluble constituent is decomposed in 24 hours against only 66% in the case of this coal. A point of inflexure in the curves for the β -cellulose substances occurs when 50% of this substance has been decomposed; the curve for the resinic bodies tends to exhibit no definite change of direction. These facts can be interpreted on the basis that the β -cellulose comprises nearly equal amounts of substances of different stability at 450° C., whilst the resinic bodies approach homogeneity. Contrasting the behaviour of these substances with the corresponding constituents of the Two Foot Nine and No. 2 Rhondda, the marked stability of the β -cellulose in this coal is very evident; moreover, the ratio of the resinic bodies to the β -cellulose substances in the residues increases much more slowly than in the case of the two first-named coals; this is due not only to the greater stability of the β -cellulose but also to a corresponding greater stability of the resins in this coal as compared with the resinic constituents contained in the other coals—a fact readily evident by comparison of the resinic curves for each coal, and emphasised by the fact that the extent of decomposition of the resins in the No. 3 Rhondda only reaches in 24 hours the same value as is reached in the case of the other coals in 2½ hours. By prolongation of the curves for the β -cellulose and resinic bodies of this coal it becomes evident that the whole of the β -cellulose will be decomposed at the end of 48 hours' treatment at 450° C., and that when this has taken place the resins will have undergone decomposition to an extent of 66% of the amount originally present in the coal.

Analyses of β -cellulose and resinic substances isolated from various residues are given in Table XV.

TABLE XV.

Residue.	β -Cellulose.		Resinic.	
	Original.	2 hours 450° C.	Original.	24 hours 450° C.
C	80.50	83.03	82.80	83.16
H	4.00	3.76	6.96	6.16
Ratio, C:H ..	20.12	17.43	11.88	12.47

The approach of the resins to homogeneity is evident from the above figures.

Nitrogen and sulphur.

TABLE XVI.

Amounts of N and S present in the residues from 100 parts of coal substance 450° C.

Hours of heating.				Nitrogen.	Sulphur.
Original coal substance	1.45	0.64
1½	1.20	0.50
3½	1.28	0.50
5½	1.27	0.51
9½	1.28	0.54
24½	1.22	0.56

It is evident from these results that approximately 14% of the nitrogen present is eliminated from this coal at 450° C., and since this occurs within the first 1½ hrs. of treatment the nitrogenous constituent decomposed is relatively unstable at this temperature. Associated with the decomposition of this nitrogenous substance is the elimination of 20% of the total sulphur present in the coal, no doubt due to the destruction of an organic substance containing sulphur of the same order of stability as the nitrogenous constituent. The elimination of pyritic sulphur at this temperature is not very probable.

No. 2 Llantwit.—Temperature 450° C.

TABLE XVII.

Percentage of constituents in residues obtained at 450° C.

Hours of heating.	Percentage in residue.			Amount in residues ex 100 coal substance.		
	Pyridine-soluble.	β -Cellulosic.	Resinic.	Pyridine-soluble.	β -Cellulosic.	Resinic.
1	31.38	23.80	7.56	31.97	24.26	7.71
1½	19.04	11.67	7.37	18.02	11.04	6.98
5	15.67	10.34	5.33	14.42	9.50	4.92
9	14.38	8.35	5.63	13.16	7.63	5.13
24	9.49	4.50	4.99	8.58	4.07	4.51

The general similarity of behaviour during the 24 hours' heating of this coal and the No. 3 Rhondda is thus evident. Residues arising from these two coals contained β -cellulosic constituents associated with the resinic substances throughout the 24 hours' heating; the ratios of resinic to β -cellulosic constituents in the residues are of the same order, and indicate a greater stability of the resinic as compared to the β -cellulosic substances. The stability of these latter constituents are of the same order and markedly distinct from that of the corresponding portions of the Two-Foot-Nine Seam and the No. 2 Rhondda. The No. 2 Llantwit undoubtedly decomposes faster in the earlier stages than does the No. 3 Rhondda. The percentage loss of constituents is represented graphically in Fig. 4.

Fig. 4.

from which definite points of flexure are evident in the curves for both the resinic and β -cellulosic substances. The β -cellulose appears to consist of two types of substance in equal amounts, and compared with that of the No. 3 Rhondda this constituent is less stable since it is decomposed to a 10% greater extent for the same duration of heating than in the case of the latter coal. The more stable portion of the resinic substances is more stable than the stable resin of the No. 3 Rhondda, and it represents a resinic practically stable at 450° C. Subsequent results of this investigation reveals a marked difference in properties of these two types of resin.

TABLE XVIII.

Residue.	Original.	5 hours 450° C.
C	83.37	84.53
H	7.71	7.15
Ratio, C/H	10.81	11.82

The analyses of resinic substances isolated from various residues are given in Table XVIII.

Nitrogen and sulphur.

TABLE XIX.

Amounts of N and S present in the residues from 100 parts of coal substance. No. 2 Llantwit, 450° C.

Hours of heating.	Nitrogen.		Sulphur.	
	%		%	
Original	1.49	2.08	1.40	1.72
1	1.40	1.72	1.39	1.56
5	1.42	1.40	1.42	1.40
24	1.38	1.22	1.38	1.22

These results show that a nitrogenous substance is decomposed in the early stages of the decomposition of the coal substance. Constituents containing "organic" sulphur are undergoing decomposition throughout the whole period of decomposition.

Examination of stability of β -cellulose and resinic at 350° C., No. 2 Llantwit.

The examination of the residues resulting by heating charges of the No. 2 Llantwit at 350° C. and the No. 3 Rhondda at 400° C. for various times was next undertaken with a view to determine with greater exactitude the difference in stability of the β -cellulose relative to the resinic constituents in each of these coals. The following results were obtained, from which were calculated the amounts of the constituents present in the residues resulting from 100 parts of coal substance.

TABLE XX.

Constituents in residues from No. 2 Llantwit at 350° C.

Hours of heating.	Percentage in residue.			Amount in residue ex 100 coal substance.		
	Pyridine-soluble.	β -Cellulosic.	Resinic.	Pyridine-soluble.	β -Cellulosic.	Resinic.
1½	23.74					
2½	20.90*					
4½	21.79	12.47	9.32	22.55	12.90	9.65
10½(a)	29.36	19.98	9.38	28.80	19.60	9.20
(b)	27.21					
	27.00	17.70	9.30	26.87	17.62	9.25

* On repeating heating operation loss of wt. = 2.11%.

The anomalous results in the case of the residues resulting in the two early periods of heating are rather remarkable. The total repetition of the determination for a period of 2½ hours gave practically the same results. A similar anomaly is evident in the case of the No. 3 Rhondda at 450° C. The effect of various temperatures below the temperature of decomposition of the coal upon the amount of substance extractable from a coal is under investigation; until this work is completed the anomalous behaviour may be explained as arising from the following causes: The amount of substance soluble in pyridine obtained from any coal that has been heated above its "decomposition point" is the resultant of two opposing factors; one, due to the "unbinding" of the coal structure, results in an increase of soluble constituents; the other produces a decrease of pyridine-soluble constituents by virtue of the destruction of substances which in the unheated coal are soluble in pyridine. The net result will depend upon the relative velocity with which these opposing factors operate. It is apparent from the above results that the β -cellulosic constituent is decomposed more rapidly than the

resinic substances, which appear to be practically stable at this temperature. No doubt the portion of the β -cellulose here destroyed is that portion rapidly decomposed at 450°C .

No. 3 Rhondda, 400°C .

TABLE XXI.

Constituents in residue from No. 3 Rhondda,
Temperature 400°C .

Hours of heating.	Percentage in residue.			Amount in residue ex 100 coal substance.		
	Pyridine- soluble.	β -Cellu- lose.	Resinic.	Pyridine- soluble.	β -Cellu- lose.	Resinic.
1	32.53	21.23	11.30	32.86	21.46	11.66
2	38.48	25.70	12.76	37.63	25.14	12.14
4	36.60	23.60	13.00	35.60	22.96	12.64
10	22.60	11.85	10.75	21.02	11.03	10.00

The β -cellulose is thus more readily decomposed than the resinic substances. The amount of resinic substance found in the coal substance by direct extraction was equal to 14.07%; the half-hour residue at 450°C . contained only 11.21%. At least 2 or 3% of the resinic substance is therefore rapidly decomposed. The increase of the values for the β -cellulose in the residues resulting from heating the coal for periods up to 4½ hours at 400°C . indicates that the "unbinding" of the coal substance renders an enhanced amount of β -cellulose soluble in pyridine. This is very unstable at 450°C ., since the half-hour residue at this temperature only contains 19.93%. It is hoped that work now proceeding on the extraction of the various coals by Harger's method (heating with pyridine at about 150°C .) will give more reliable data as to the amounts of the various substances present in the coals. The values obtained for the various half-hour residues are shown by the experiments now to be described to constitute a definite basis for the discussion of the various series of results at 450°C . and their bearing upon the coking qualities of the coals.

TABLE XXII.

Pyridine and volatile matter evolved at 450°C .
from the residues from the pyridine extraction of
"cokes."

Residue.	1 hour loss at 120°C .	Total volatile 450°C .	Total pyridine evolved, 450°C .	Equivalent volatile in original coal.
½ hour 450°C .				
No. 2 Llantwit ..	0.50	10.21	7.56	1.41
2 hours 350°C .				
No. 2 Llantwit ..	0.50	18.26	7.75	8.21
½ hour 450°C .				
No. 3 Rhondda ..	0.58	9.35	3.14	4.14
½ hour 450°C .				
No. 2 Rhondda ..	0.31	1.64	1.41	0.12

To determine if the decomposition of these coals was in conformity with the results obtained by Wheeler with other coals, namely, that decomposition below 500°C . was concerned with the destruction of the pyridine-soluble substances, that portion of the half-hour residue (450°C) insoluble in pyridine was washed repeatedly with dilute hydrochloric acid and then with water until it was free from acid, and the washed residue dried for eight hours at 105°C . in *vacuo*. One gram. of the residue was then heated in a porcelain combustion boat at 120°C . in nitrogen for one hour, and the loss of weight determined. The boat and its contents were next heated at 450°C . in a current of nitrogen for three hours, the products evolved were collected in standard acid, and the boat and its contents cooled in nitrogen.

Other workers have suggested that pyridine combines with the coal substance. A very pronounced smell of pyridine was observed in blank experiments at 450°C ., moreover a solution in water of the vapours evolved gave a distinct precipitate with picric acid; consequently the equivalent of the acid neutralised was calculated in terms of pyridine. The results obtained with the various residues are given in Table XXII.

Fig. 5.

Fig. 6.

Fig. 7.

The individual coals yielded no products soluble in 10% aqueous caustic potash, and hence no ulmin

compounds are present in these coals. The above results show that after removal of that portion of the residue soluble in pyridine the resulting residue of the No. 2 Llantwit heated to 450° C. contains only a small amount of products decomposable at 450° C. The higher volatile figure for the two-hour residue at 350° C. is due to the β -cellulosic constituents not being rendered soluble, or not being produced as a secondary product by preheating. The close agreement between the pyridine content of the two residues from this coal indicates a similarity of chemical nature of that portion of these residues stable at 450° C., and constitutes direct evidence of the union of pyridine with the coal substance. Moreover, the decrease in "acidity" of the corresponding portions of the other coals is evident from the decrease in the amounts of pyridine in the residues. The high volatile figure of the half-hour residue of the No. 3 Rhondda may be due to the same causes as is the higher volatile figure of the 350° C. residue of the No. 2 Llantwit compared with the 450° C. residue from the same coal. The No. 2 Rhondda, from the above results, yields its maximum pyridine-soluble after the half-hour heating at 450° C. and contains no other constituents decomposable below 450° C. It is evident that in the study of the decomposition of the coals concerned at temperatures below 450° C. the major portions, if not all the products undergoing change, are those soluble in pyridine, and further that the volatile matter expelled from any coal during a given period at 450° C. may be regarded as arising from the destruction of the pyridine-soluble substances.

The individual curves representing the decomposition at 450° C. of the pyridine-soluble, β -cellulosic, and resinic constituents of the several coals are grouped in Figs. 5, 6, and 7 respectively, from which the general relative ease of decomposition of these constituents becomes evident.

The main results of this investigation are as follows:—

- (1) The decomposition of the coals at temperatures up to 450° C. results in the destruction of the pyridine-soluble constituents of the coal substance.
- (2) The stability of the pyridine-soluble constituents in the coals examined is in the following order of decreasing stability:—No. 3 Rhondda, No. 2 Llantwit, Two-foot-Nine, No. 2 Rhondda (see Fig. 5).
- (3) The decomposition of the pyridine-soluble constituents results in a more rapid decomposition of the β -cellulosic substances than of the resinic compounds. In all probability the β -cellulosic constituents are the first to decompose.
- (4) Two types of β -cellulosic and resinic compounds occur in each of the coals examined; (a) one type is readily decomposed at 450° C., (b) the other type is comparatively stable at this temperature.
- (5) The typical coking coals contain an approximately homogeneous β -cellulosic class of substance readily decomposed at 450° C., whilst the other coals examined contain nearly equal amounts of the two types enumerated under (4) (see Fig. 6). These facts are generally characteristic of the resinic substances in these coals, although the homogeneity of the resins is not so well marked in the true coking coals (see Fig. 7).
- (6) The stability of the β -cellulosic relative to the resinic compounds is more pronounced in the No. 3 Rhondda and No. 2 Llantwit than in the typical coking coals.
- (7) The progressive decomposition of the β -cellulosic and resinic substances in the case of the coking coals results in a rapid increase of the

ratio of resinic to β -cellulosic constituents. In the other coals the increase of this ratio is very gradual.

- (8) Progressive decomposition of the coal substance at temperatures not exceeding 450° C. will ultimately result in a residue devoid of β -cellulosic substance but one which still contains resinic substances.
- (9) Nitrogenous compounds in the coal are destroyed; at 450° C. the nitrogen eliminated represents approximately 10% of the total nitrogen present in the coal.
- (10) Sulphur compounds are more readily decomposed in the highly bituminous than in the less bituminous coals, certain of which do not evolve volatile sulphur compounds at 450° C.

Edinburgh Section.

Meeting held at Edinburgh, on February 27, 1920.

DR. D. S. JERDAN IN THE CHAIR.

RATE OF CORROSION OF ALUMINIUM.

BY G. H. BAILEY, D.SC., PH.D.

The author introduced his subject by pointing out that the large bulk of the work done in this direction gave entirely fallacious results owing to the fact that alteration in weight during corrosion afforded in itself no trustworthy information. He then dealt with methods of procedure based upon methods formulated and published (Bailey, J. Inst. Metals, 1913, 9, 79). Having recounted the steps to be taken and the precautions to be observed, he showed that a definite measure of the extent to which a sample of aluminium had been corroded, in terms of the metal so corroded per day per 100 sq. cm. of surface, was given by

$$CR = \frac{3}{8} (S + w - W)$$

where W was the weight of the sheet employed, w its weight after exposure, and S the weight of the precipitate obtained from the corrosive liquid after ignition.

It was pointed out that a prolonged and varied series of experiments had been carried out, extending over a period of nearly ten years, which had fully confirmed the value of this method of estimation.

Typical results were then quoted as to the effect of temperature, time of exposure, concentration of the corrosive medium, deposits on the metal and other variables. For most of the details relating to the method his original paper (*loc. cit.*) may be consulted.*

Diagram 1 summarises the results of experiments carried out with a view to ascertain the effects of concentration of the liquid reagent. It is plotted in logarithmic terms to show more clearly the behaviour of the lower degrees of concentration, and some remarkable effects of higher concentration are also apparent.

Some observations were then made upon the effects observed when the liquids used were at high and even boiling temperatures, under which conditions the phenomena exhibited were by no means comparable with those shown at ordinary temperature, though in many respects considerable analogy was apparent.

[The remainder of the paper follows in *extenso*.]

* A correction has been made in the formula there given for which the author is indebted to the timely criticism of Mr. G. Cecil Jones.

In practice, at ordinary temperatures, the amount of reagent taken is always largely in excess of that which can be reacted upon during the period

imposed by the accepted equations for their reaction with aluminium. But if the residual liquid from this reaction be raised to say 50° C. its activity is restored and a very distinct corrosion takes place in both cases.

Aluminium placed in contact with 200 c.c. of N/1 (3.6%) hydrochloric acid at 95° C. dissolved rapidly and continued to do so over a prolonged period. The liquid became more viscous but remained translucent, until the relationship of the chlorine to aluminium reacted upon, approximated to that required by the formula $Al_2(OH)_2Cl$. It was, however, materially changed in character and had become not only viscous but strictly colloidal. On further continuing the experiment (for the rate of corrosion was still very pronounced) turbidity appeared, and this rapidly grew to a bulky gelatinous precipitate containing very little chlorine and corresponding to the formula $Al_2(OH)_4Cl$. The corrosive activity was still manifest, and apparently it is possible to carry on the reaction indefinitely with a quantity of hydrochloric acid which, at ordinary temperatures, would react only upon a very small fraction of the aluminium exposed.

Similar effects were found with other acids and have been observed by Seligman and Williams (this J., 1917, 409) in the case of acetic acid. The solid product ultimately obtained is hydroxide of aluminium, whilst the free acetic acid (200 c.c. of a 2% solution was used in my experiments) remains practically unchanged in amount and is still active.

Such effects cannot be, of course, of the same order as experiments conducted with a large excess of the acid at ordinary temperatures, and appear to be mainly the results of oxidation through the intermediary of basic salt production and afford a prelude to the last section of my paper.

The protective coating formed during corrosion.

We have seen already that when the exposure of metal to a liquid has been somewhat prolonged there is a very distinct decrease in the rate of corrosion resembling the parallel case of metallic lead. Independent experiments have shown that this cannot be attributed to a loss of concentration in the reagent. Nor is it attributable, otherwise than exceptionally, to the diluent or inhibitive action of the soluble by-products which may be

Diagram 1.

of exposure. The question as to when the limit of activity will be reached by reason of the exhaustion of the reagent or the effect of its reduced concen-

Diagram 2.

tration upon the rate of corrosion is of some interest. For instance, to take two quite different reagents, caustic soda and hydrochloric acid become exhausted and cease to show corrosive action at ordinary atmospheric temperatures at the limit

formed. In mineral acids of medium concentration only soluble products are formed, but in the majority of cases solid products consisting chiefly of alumina and small amounts of the oxides of iron and silicon separate as the result of oxidation and

remain either in suspension or attached to the metallic surface. Thus is formed the protective coating which, of course, interferes with the direct action of the reagent and reduces the rate of corrosion.

Such reduction is much more marked with impure metal than with that of high purity because in the initial stages the rate of corrosion is greater in metal of low purity, so that not only is there more alumina formed but still more of the other oxides.

The result is manifest and I append, merely as one example out of many, that of the course of corrosion when two samples of aluminium, the one of the highest purity, 99.7%, and the other metal of 98.8% purity, containing nearly 0.9% of iron. These were exposed over a prolonged period (nearly four days) to a solution of ammonia of N/1 concentration (1.8% NH_3).

Experimental means were devised for estimating the amount of corrosion and the amount of the adherent deposit at frequent intervals. The accompanying diagram shows the results of the investigation in a typical case. The amount of the adherent deposit is shown by the broken curves which are on a vertical scale such that the maxima are, for 98.8% metal (0.9% Fe) 240 mgrms. per 100 sq. cm. of surface, and for the high purity metal 50 mgrms. The larger of these deposits is a mere film about 0.01 mm. in thickness.

It is evident that if the deposit be allowed to remain upon the metal the rate of corrosion at the end of the period is reduced about five-fold owing to the protection afforded. This opens up possibilities in the way of applications to the arts and manufactures by which the effects of corrosion may be minimised. Already, by the use of special means important developments have arisen from the facility with which a thin oxidised film on the surface of aluminium has afforded perfect insulation under tolerably high tension electric currents, and the same principle may find application in the protection of chemical plant against corrosion. Aluminium alloys containing a small percentage of copper show this property of self-protection against corrosion and open up the possibility of advantage coupled with the application of metal having a much higher tensile strength than that of aluminium itself. Proceeding on the basis laid down, it will be manifest that by modifying the course of procedure and introducing corrections in the expressions made use of in the calculations, metals such as zinc, copper, iron, etc., and even alloys such as brass may be subjected to similar methods of investigation with considerable precision.

Additional.

The following observations at atmospheric temperatures are from various sources and have been nearly all confirmed or corrected by the author of this paper. The results which appear in the foregoing diagram are not included. They have been classified in such a manner as to condense the statement as far as possible, and where values for CR need to be given these are placed in parenthesis and are for 15° C.

I. Substances whose CR is practically negligible.

(a) *Gases*.—Air or oxygen, carbon monoxide and dioxide, chlorine, hydrogen sulphide, sulphur dioxide: all unsaturated with water.

(b) *Organic compounds*.—Acetone, alcohol and alcoholic beverages, antiseptics, benzol, citric acid, ether, oils, fats and fatty acids generally (if free from mineral acid), formaldehyde, glycerin, gelatin, salicylic acid, saliva, tannic and gallic acids, tartaric acid, phenol (even in solid state or alcoholic solution), lactic acid.

(c) *Aqueous solutions*.—Boric acid, salts of alkalis and alkaline-earths, except when alkaline or acid in reaction; also salts of many other metals.

II. Substances whose aqueous solutions show

higher corrosive properties.—Salts of copper, iron, mercury, lead, silver, etc.; hydroxide of calcium and other hydroxides of alkalis and alkaline-earths; sodium aluminate, sp. gr. 1.13, highly alkaline; oxalic acid (4.5% solution, CR=5.9); hydriodic acid; hydrofluoric acid; ammonium chloride (5.35%, CR=5.6); sodium fluoride (saturated solution, CR=9.3); sodium chloride (saturated solution, CR=12.0); calcium chloride and potassium chloride, also iodide, have, however, very slight action.

Liverpool Section.

Meeting held on April 22, 1920.

DR. E. F. ARMSTRONG IN THE CHAIR.

CATALYTIC ACTION AT SOLID SURFACES: SOME FACTORS CONTROLLING THE RATE OF HYDROGENATION OF ETHYLENIC COMPOUNDS IN PRESENCE OF NICKEL.

BY E. F. ARMSTRONG, D.SC., AND T. P. HILDITCH, D.SC., F.I.C.

The technique of the catalytic hydrogenation of liquid organic compounds is sufficiently well understood to permit investigations of the chemical kinetics of the action to be carried out with considerable precision. Of all surface actions it is probably that best adapted to treatment of this kind, since the progress of hydrogenation may be followed directly by measurements of the absorption of hydrogen, whilst the action is suitably rapid and may be studied over a range of temperature at which constancy of the latter factor is comparatively easily maintained.

With the exception of a few measurements of rate of hydrogenation of organic compounds in presence of colloidal palladium or platinum, however, work of this type has hitherto been concerned with the saturation of the mixture of glycerides present in natural oils, where it has been difficult to study the hydrogenation of a single chemical individual.

In most of the studies of the rate of hydrogenation of unsaturated fatty oils which have appeared within the past few years the main action is referred to the unimolecular or "logarithmic" type, in which the same fraction of the substance present at a given moment is changed in successive equal intervals of time, and which is expressed mathematically as

$$dx/dt = k(a-x) \text{ or } k = 1/t \log a/(a-x)$$

where a = total volume of hydrogen required to saturate the glyceride present. For example Fokin (*Z. angew. Chem.*, 1908, 22, 1451, 1492) states that the reduction is to be included in the category of unimolecular reactions, but that the curves often show a straightening out towards the abscissa axis.

Moore, Richter, and van Arsdel (*J. Ind. Eng. Chem.*, 1917, 9, 451), who studied the incomplete hydrogenation of cotton-seed oil, found that the linolein present hydrogenated very much more rapidly than olein, and that the relative speeds of hydrogenation of the two glycerides could be varied within limits by alteration of temperature or pressure. The relation between fall in iodine number and time is stated to take the form of curves showing a general similarity to a logarithmic curve, but "flattening out sooner than expected in every case, as though the catalyst was losing its activity."

Ueno (*J. Chem. Ind. Tokio*, 1918, 21, 749) concluded that the rate of hydrogenation of fatty oils is expressed by the simple unimolecular mass-action equation given above.

Ubbelohde and Svanoe (Z. angew. Chem., 1919, 32, 257, 269, 276) have compared the general efficiency of various types of hydrogenation apparatus, and have noted that linolein yields a mixture of oleins (ordinary olein and "iso-olein") on hydrogenation. Moore has made the further observation (this J., 1919, 320) that ordinary olein (the glyceride of liquid oleic acid) itself is partially transformed during hydrogenation into "iso-oleins" (derived from elaidic and solid iso-oleic acid).

Fig. 1.

Thomas (this J., 1920, 10 r), employing a closed apparatus, has given a mathematical analysis of observations upon the rate of hydrogenation of olive oil (consisting mainly of tri-olein) based upon the unimolecular mass-action equation, and allowing for the simultaneous proceeding of the two hydrogenations—that of linolein and that of olein. The unimolecular constants he obtained are in good agreement with the experimental data.

On the other hand, experiments previously described by us (Proc. Roy. Soc., 1919, A, 96, 137) with olive, cottonseed, linseed and whale oils, in which the hydrogen was continuously passed through the hydrogenation apparatus, and the absorption measured at short intervals by meter readings before and after passage through the latter, showed that oils from various sources are hydrogenated, broadly speaking, at a constant rate until only about 10–20% of glycerides more unsaturated than olein is left, after which an abrupt change occurs. Soon, however, the rate settles down again to approximate constancy; then, after an interval, it gradually declines as a state of saturation is approached.

From the mainly linear nature of the curves thus obtained, it was concluded that the action which was actually measured represented the decomposition by hydrogen of an unstable complex formed between nickel and the unsaturated compounds. The first process was held to be a relatively fast equilibrium action, with the balance strongly in favour of the unassociated constituents, whilst the second (measured) action was relatively slow. It is important to bear in mind that, in any study of the velocity of a chemical change, only the

slowest of a series of actions taking place at the same time is being measured.

In all such cases it is of first importance to obtain the correct chemical interpretation of the mathematical results, for the latter, after all, serve only to interpret the form of the curve which represents the general relation between the chemical action and the time taken, and do not necessarily point to the reason which causes the curve to take a particular form. There is thus at present a conflict of evidence between logarithmic and approximately linear relations for the amount of hydrogen absorbed/time.

Now, a logarithmic curve represents a continuous decline in the amount of chemical action as time progresses, whereas a true linear curve represents chemical action as independent of the progress of time. Consequently, an approximate linearity indicates that the action, after a given time, has proceeded to a greater extent than if it was of the logarithmic type. It is certain, then, that a true logarithmic action could not approach linearity owing to any abnormal decline of catalytic activity, since this would deflect the curve still further towards the horizontal (time) axis. It should be emphasized that the absolutely linear portion of our curves extends well beyond the limits of experimental error; thus, in the case of various hydrogenations in presence of nickel, the following table shows the relation between the total absorption of hydrogen obtained, and the time taken, to the absorption of hydrogen and time occupied in tracing the initial completely linear portion of the curve:—

Unsaturated compound.	Temp. ° C.	Total hydrogenation.		Initial linear portion.	
		Litres H ₂ absorbed in mins.		Litres H ₂ absorbed in mins.	
Cottonseed oil	180°	30.3	73	12.8	17.7
Linseed oil ..	180°	22.9	59	10.4	13.8
" ..	140°	19.0	69	9.3	24.8
" ..	230°	22.7	56	9.9	9.5
Ethyl cinnamate	140°	12.55	29.7	11.25	23.4
" ..	180°	12.55	22.4	10.25	15.9
Anethol ..	140°	13.15	49.9	7.50	20.3
" ..	180°	13.40	30.3	10.10	18.6

The absolutely linear portion may thus occupy from 40 to over 80% of the total absorption of hydrogen, and from 15 to over 60% of the total time occupied by the action.

On the other hand, it is obvious that the action could not possibly express itself in a linear form throughout its whole course, for the following reasons:—

(i.) As previously pointed out (Proc. Roy. Soc., A., 1919, 96, 137), the diminution of the amount of unsaturated compound must eventually affect the equilibrium

(ii.) The evidence which goes to show (*ibid.*, 1919, 96, 322) that the action

although feeble at 180° C., is in certain cases sufficient to permit of the transference of hydrogen from a saturated molecule of one species to an unsaturated molecule of another indicates that the saturated grouping—CH₂CH₂—when present in sufficient concentration (*i.e.*, towards the close of the action) may commence to compete with the diminished amount of unsaturated compound in the equilibria set up with nickel.

(iii.) As in all these actions, by-products more or less toxic to the catalyst will gradually accumulate, and tend to exert a definite influence (although but small in the hydrogenation of highly purified com-

pounds) upon the activity of the nickel and the speed of the action.

Many investigators in this field have employed a closed type of reaction-apparatus from which no gas escapes during the action, so that any volatile products, toxic or merely inert, must accumulate in the system.

Experiments are quoted later which were conducted with the same apparatus, but in which the customary method of operating (with a free passage of hydrogen) was replaced by a "closed" system in which the hydrogen was simply drawn in to replace absorbed gas as the action proceeded. The results emphasise the extent to which traces of gaseous impurities will accumulate when a relatively large volume of hydrogen is absorbed with only a small closed gas-space, and show that it is necessary under these conditions to pay due attention to the altering concentration of hydrogen in the gas-space.

The study of the hydrogenation of some synthetic ethylenic compounds has been undertaken since these substances are not only entities themselves, but are more easily purified than the glycerides and possess only one ethylenic linkage. The compounds employed, which were carefully purified by fractional distillation in a vacuum before hydrogenation, were: ethyl cinnamate, $C_6H_5.CH:CH.COOC_2H_5$, and anethol, $CH_3O.C_6H_4.CH:CH.CH_3$. For comparison with our present data, the curves (fig. 1) obtained in hydrogenating, at 180° C. in presence of 0.2% of nickel, olive, cotton-seed, linseed, and whale oils are reproduced. Olive oil contains but little linolein, cotton-seed about 50% linolein and 25% olein, linseed oil about 20% olein, and the remainder mainly linolein and linolenin, whilst whale oil contains too complex a mixture of glycerides of acids of varying degrees of unsaturation to be of any utility for the present purpose.

I. Hydrogenation of ethyl cinnamate and of anethol at 140° and 180° C.

100 grms. of each of these compounds was hydrogenated in presence of 0.15 gm. of nickel under conditions comparable to these in the hydrogenation

Fig. 2.

tion of oils (*loc. cit.*), a flow of electrolytic hydrogen of 50 litres per hour being maintained in all cases.

The data are shown graphically in fig. 2 (hydrogen

absorbed in litres as ordinates against time in minutes as abscissæ), and are also reproduced in the tables. The latter give details of time in minutes (t) and hydrogen absorption in litres (v), with the respective constants for a linear relation ($K=v/t$) and for a unimolecular action,

$$K' = 1/t \log V'/(V'-v).$$

V' represents the total volume of hydrogen (measured at the temperature of the meter) required to saturate 100 grms. of the organic compound.

For ethyl cinnamate (meter temp. 19°) $V'=13.60$, and for anethol (meter temp. 15.5° C.) $V'=16.00$.

II. Hydrogenation of ethyl cinnamate and anethol at 180° C.—"closed system."

The hydrogenations at 180° C. were next repeated under somewhat different conditions—the usual exit of the apparatus was connected to the hydrogen supply through one of the meters (the former gas inlet being closed), thus connecting the gas-space above the hydrogenation system to the gas supply, and hydrogen was drawn in as the action proceeded to replace that which had been absorbed.

The results were different from those previously obtained and, when plotted (fig. 3), were found to give curves frequently closely related to the logarithmic type. Experiments were made in each case with undried hydrogen and with hydrogen passed over a long layer of calcium chloride granules, with numerical results as given on next page.

These results are typical of a number of experiments; some give increasing unimolecular "constants," others moderately concordant values, and others (notably those with undried gas) give "constants" which eventually decline considerably. On resuming hydrogenation by the continuous gas-flow method, the usual approximately linear graphs had been employed the rate was found to have declined—i.e., the catalyst had lost activity.

remaining experiments were confined to the case of ethyl cinnamate, which was proved to yield ethyl β -phenylpropionate quantitatively both at 180° and 140° C.

It was natural to consider whether the action was likely to proceed by a different mechanism merely by altering the mode of admission of hydrogen to the system, or whether the small amount of gaseous impurities present in the hydrogen or emanating from the organic compound diminished the concentration of hydrogen in the gas-space notably.

If S is the total gas-space available, v the volume of hydrogen absorbed at time t , and P the percentage of hydrogen in the gas employed, the volume of gaseous impurity in the gas-space when v litres have been absorbed is $v(100-P)/P$, so that concentration of H_2 in gas-space at time t

$$= \frac{P}{100S} \left(S - \frac{100-P}{P} \cdot v \right)$$

Assuming the rate of absorption is proportional to this concentration,

$$\frac{dv}{dt} = \frac{KP}{100S} \left(S - \frac{100-P}{P} \cdot v \right)$$

S & P are constant for the same apparatus and supply of hydrogen so that this may be written in the form

$$dv/dt = K''(V'' - v)$$

where $V'' = PS/(100-P)$, i.e. = the total volume of hydrogen which can be absorbed before the gas-space is completely filled with impurities.

$$\text{Hence } K'' = 1/t \log V''/(V'' - v).$$

On attempting to apply this hypothesis to results of the type indicated above, it was found that in some cases more hydrogen had been absorbed than the value V'' permitted, possibly in consequence of diffusion in the connections during the slower stages of the absorption.

A further series of experiments was therefore made, in which carefully dried hydrogen was employed as before, and a long capillary tube inserted between the drying-tube and the inlet to the hydrogenation apparatus.

It was calculated that a flow of only 0.02 litre per minute through the capillary employed required a linear velocity of about 30 cm. per sec., so that back diffusion would be practically suppressed. The volume of the gas-space in the apparatus was measured, allowing for the volume occupied by 100 grms. of ethyl cinnamate at 180° C. (120 c.c.) and found to be 648 c.c. This volume of gas at 180° C. would occupy 412 c.c. at 15° , the temperature of the meter throughout the next series of experiments.

The percentage of hydrogen available for absorption was then calculated as follows:—In an experiment X litres of (dry) hydrogen had been absorbed. A sample of the gas in the gas-space was then extracted and analysed, and from the percentage of hydrogen (p) the volume of hydrogen in the vessel was found (x litres)

$$\text{Whence, } \% H_2 = \frac{X + x}{X + 0.412} = P$$

so that the total volume required to fill the beaker space completely with gaseous impurity ($=V''$) = $9.412P/(100-P)$ litres. Obviously, this expression takes account of impurities originally in the hydrogen and of those resulting from the organic compound, and is only strictly valid if we can assume that the latter accumulate in the same way as the former.

It was found, however, that the residual gas generally contained 2–3% CO_2 , 4–10% calculated as CH_4 & 40–60% H_2 , so that the bulk of the impurity was nitrogen, evidently from the original hydrogen. The "organic" gaseous impurities are therefore relatively small in comparison with the nitrogen.

Fig. 3.

In the other cases no perceptible diminution in rate was observed. It may be added that anethol was observed to furnish small quantities of a solid crystalline compound (at present under investigation) as well as the normal product of hydrogenation, dihydroanethol, when treated at 180° , and especially in the "closed" apparatus. Since it was desired to eliminate any possible action other than that of saturation of the ethenoid bond, the

Experiments were then made, using the "closed" apparatus, with 100 grms. of ethyl cinnamate and 0.15 gm. of nickel in each case, employing dried gas from four different cylinders of electrolytic hydrogen, with the capillary tube inserted to eliminate back-diffusion.

The next table contains the results obtained, giving

t , v , and $K = v/t$ as in the previous cases.

K' , the "unimolecular constant" calculated with respect to the total hydrogen absorbable by the ethyl cinnamate present ($V' = 13.40$ at 15°).

p , the percentage of hydrogen in the residual gas.

P , the effective percentage of hydrogen calculated as shown above.

K'' , the "unimolecular constant" calculated with respect to the total hydrogen absorbable when the accumulated impurities would occupy 648 c.c. at 180° (or 412 c.c. at 15°) (V'' calculated from P as described).

The extreme variability of V'' as P increases from 98% upwards is to be emphasised, and is a consequence of the asymptotic nature of the curve corresponding to $V'' = 0.412 P/C (100 - P)$. (V'' becomes ∞ when $P = 100\%$).

	40	12.27	0.307	0.0268				0.0112

It is deduced that:—

(i.) The excellently concordant values of K'' show that the curves obtained in a "closed" apparatus are a measure of the diminishing concentration of hydrogen in the gas-space, and have no bearing on the mechanism of the actual hydrogenation;

(ii.) With increasing purity of hydrogen the ratio v/t approaches the mainly linear type always obtained in the hydrogenation of pure compounds with continuous passage of hydrogen;

(iii.) The values of K' increase throughout, but tend to become more concordant as the purity de-

creases (in the above series they would, of course, be constant for $V' = 13.40$, i.e., "effective % H_2 " = 97.0);

Fig. 4.

(iv.) As the purity of the hydrogen and the speed of the action (measured by v/t) increase, the absolute values of the constants K'' fall; this is simply the mathematical expression of the fact that the "rate of reaction" really measured is that at which the gas-space is being filled with gases other than hydrogen—the rate being smaller the purer the hydrogen.

The data given in this paper therefore show that:—

(i.) with free passage of hydrogen an ethylenic compound is hydrogenated in the liquid state at a rate which, for more than half of the complete action, is independent of the concentration of the unsaturated compound

(ii.) in a closed system, the rate is governed by the decreasing concentration of the hydrogen above the liquid, caused by the accumulation of gaseous impurities from the hydrogen and (to a less extent) from the organic compound.

The additional facts now brought forward appear considerably to strengthen the theory that catalytic hydrogenation may be represented by the scheme:—

(relatively fast equilibrium in the general sense indicated by size of arrows).

(relatively slow, measurable action).

It is plain that progressive alteration of the hydrogen concentration must affect the rate at which the second phase of the change proceeds.

In conclusion, without attaching undue finality to Irving Langmuir's suggestive view that "adsorption" is conditioned by a single layer of molecules held at a surface by forces which are none other than chemical in nature (*J. Amer. Chem. Soc.*, 1916, 38, 2221; 1918, 40, 1361), it may be stated that this view of adsorption is indistinguishable from unstable chemical combination of the kind which, according to our view, is concerned in the mechanism of catalysis of organic compounds at the surface of metals or metallic oxides, and which sixteen years ago was similarly used by one of us (*Proc. Roy. Soc.*, 1904, 73, 500) to explain the hydrolytic action of colloidal enzymes.

We would add an expression of our indebtedness to Mr. J. Allan for criticism and general discussion of the results obtained throughout the progress of these experiments.

Communication.

THE ACCELERATION OF VULCANISATION.

BY D. F. TWISS AND S. A. BRAZIER.

Three methods are available for the speeding-up of the vulcanisation process: (1) raising the temperature, (2) increasing the proportion of sulphur relative to rubber, (3) introducing an accelerator.

Effect of temperature.

The effect of alteration of temperature is similar to that for other chemical reactions, the temperature coefficient being between 2 and 3 (for 10°C.). The suggestion has been made that some accelerators, lead oxide in particular, are not genuine catalysts, but that they merely react with part of the sulphur with evolution of heat, thereby raising the temperature of the reacting mass above that of the surrounding heating medium (Seidl, *Gummi-Zeit.*, 1911, 25, 710, 748). The insufficiency of this explanation is evident from the fact that such an effect should be almost negligible at the surface of the rubber in contact with the moulds, whilst in the interior it would be marked; thick slabs also would vulcanise much more rapidly than thin sheets; both these consequences of the theory are contrary to experience. It is quite possible, however, that many vulcanisation accelerators do exert a slight thermal effect in addition to their purely catalytic influence.

The curves given in Fig. 1 represent results of some of our experiments as to the rate of vulcanisation at temperatures ranging from 138°C. (35 lb. steam pressure) to 168°C. (95 lb.) for a mixture of pale crêpe rubber (90) and sulphur (10); the corresponding curves for 128°C. will be found in Fig. 4. Pale crêpe rubber was chosen as showing greater uniformity in rate of vulcanisation than other forms of rubber, and was taken as far as possible from one case. For the introduction of the sulphur a stock mixing of sulphur with approximately an equal weight of rubber was used; the composition of this mixture was checked by analysis, and the correct proportion weighed out for mixing with the remainder of the rubber. In this way the almost inevitable loss of sulphur dust during the customary method of mixing was avoided.

The progress of vulcanisation may be followed in at least three different ways: (a) by the combination of sulphur; (b) by the gradual decrease in the extensibility of the rubber at a definite load (or increase of the load necessary to produce a definite elongation); within the range of the experiments in this paper, this shows a roughly rectilinear relationship with the period of vulcanisation. Unfortunately, this method is influenced to a greater extent than either (a) or (c) by the mechanical treatment of the rubber during mastication and the subsequent mixing operation, increased working or heating having a tendency to exaggerate the extensibility figure. The approximation of the curve to a straight line and the close proximity of extensibility values for duplicate samples (see p. 130 r) are evidence of the considerable degree of accuracy attainable with careful working. For the purpose of comparison between different samples an elongation of 600% (including the original length) at a load of 0.5 kilo. per sq. mm. has been arbitrarily assumed as a standard throughout this paper; (c) by the time required to produce maximum tensile strength.

The last method, although of less importance than might be expected in technical practice, is of considerable value in experimental work as supplying a convenient and rapid method for comparing rates of vulcanisation, e.g., of different rubbers or at different temperatures, the maximum tensile

strength, determined within three days of vulcanisation, being observed with a product containing approximately 5% of combined sulphur calculated on the rubber. The actual value of the breaking strength of a rubber test piece is always more or less fortuitous; however, as vulcanisation beyond the condition necessary for the attainment of the maximum strength causes a very rapid weakening, the position of the maximum is relatively easily determined. The peaked curves in Fig. 1 indicate the position of the maximum rather than the actual magnitude of the values.

It will be observed that the temperature coefficient manifests no tendency to any regular increase or decrease with rise of temperature, the mean value calculated (by all three methods of comparison) from the figures represented in the curves for the rubber-sulphur mixture at 123° to 168°C. approximating to 2.3.* This appears to indicate that the allotropic forms ordinarily present in molten sulphur in relative proportions dependent on the temperature, must possess equal or at least comparable vulcanising activity (see Twiss, Annual Report, 1919, 4, p. 327).

The extent to which the vulcanisation period in technical work can be reduced by raising the temperature is limited by various considerations, not the least of which is the poor thermal conductivity of rubber and the consequent danger of unequal heating, involving local irregularities in the degree of vulcanisation.

Increase of proportion of sulphur.

Many old compounding ingredients and specifics of the rubber trade, often bearing fanciful names, contained—undeclared—considerable proportions of free sulphur; mixtures of sulphur with various waxes and also with antimony sulphide may be quoted as better class examples. As the rate of vulcanisation of rubber-sulphur mixings containing less than, roughly, 10% of free sulphur is directly proportional to the percentage of free sulphur, the effect of such additional sulphur-containing ingredients on the rate of vulcanisation is obvious, and to-day is commonly realised.

For experimental work on the relative rates of vulcanisation of different rubbers or on the effect of various catalysts, the selection of a mixture of rubber and sulphur containing as much as 19% of the latter is advisable, not only because this quantity is more than sufficient to permit the progress of the change to well beyond the characteristic maximum strength, but also because it is sufficiently high to reduce in extent any disturbance arising from slight inaccuracies in the proportion of sulphur present. The possibility must always be borne in mind, however, that the activity of an accelerator may possibly be influenced by the proportion of free sulphur simultaneously present.

Use of a catalyst.

Almost all basic substances can act as catalysts to the vulcanisation process, e.g., magnesium oxide, lead oxide, lime, sodium hydroxide, potassium hydroxide, and also substances such as sodium amide, potassium glyceroxide and sodium phenoxide, which, by interaction with the traces of water invariably present in rubber, are able to give rise to alkalis or bases; typical examples of organic accelerators are piperidine, quinine (the crude alkaloid mixture known as "quinoidine" is commonly used), aniline, naphthylamine, *p*-phenylenediamine, hexamethylenetetramine, anhydroformaldehydeaniline, benzylideneaniline, aldehyde-ammonia, and simple carbon bisulphide or

* On account of the inconveniently rapid progress of vulcanisation at 168°C. and its slowness at 128°C. the measurements at 138°C. to 158°C. are possibly to be preferred; a mean value of 2.6 is then obtained for the temperature coefficient.

Fig. 1.

Fig. 2.

Fig. 3.

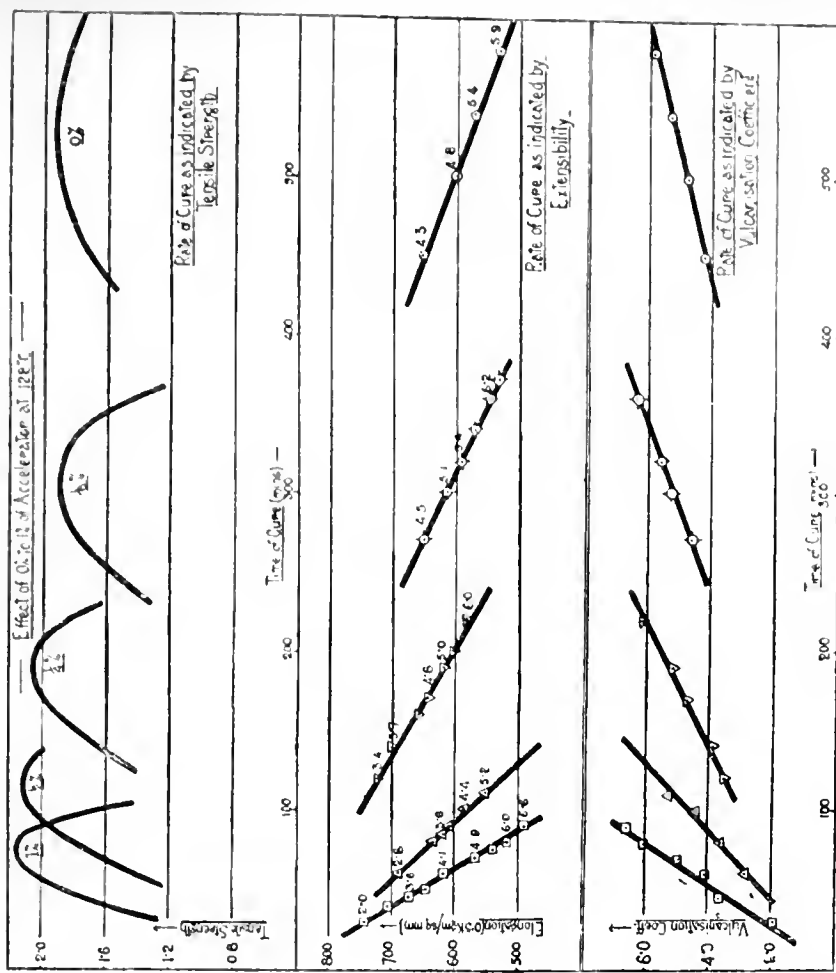

Fig. 4.

clot, freshly coagulated from the latex, is kept for several days before being rolled and washed, partial decomposition of the nitrogenous constituents of the retained serum sets in with the formation of organic bases. These are not eliminated by the subsequent rolling and washing, so that the resulting rubber exhibits exceptionally rapid vulcanisation.

As is illustrated clearly by our results in Fig. 1, the curve representing the rate of combination of rubber and sulphur does not follow the course expected from a simple chemical reaction, but, with less than 10% of free sulphur, is approximately rectilinear until the almost complete exhaustion of the sulphur (Spence and Young, this J., 1911, 817; 1912, 81, 785). This is probably to be explained by the occurrence of autocatalysis; with mixtures of rubber and sulphur containing more than 10% of the latter, the progress of the fixation of sulphur follows the sinuous S course, which is commonly regarded as characteristic of an autocatalytic process (Skellon, Rubber Industry, 1914, 172; van Iterson, Comm. Nederlands Govt. Inst. for Advising Rubber Trade, 1916, 7, 247). In the presence of an artificial catalyst, therefore, the compensation relation between the effect of the disappearance of sulphur and the extent of the increasing catalytic effect may be disturbed, so that the fixation of sulphur no longer follows a rectilinear course (van Iterson, *loc. cit.*).

Although the results as to the rate of vulcanisation of a simple sulphur mixing, as decided by these three methods, are comparable, in the presence of an extraneous catalyst, this is not necessarily so. The chemical action of sulphur on the rubber induces the physical alterations which constitute the advantage to be gained by vulcanisation, but the chemical and physical processes are not necessarily strictly proportionate, and some "accelerators" influence one more than the other. In the presence of certain accelerators the physical or mechanical alteration is disproportionately rapid, and the tensile strength attains its maximum* at a coefficient of vulcanisation (comb. sulphur $\times 100 \div$ rubber) well below the normal value of 5 (see p. 130 T).

Other accelerators, on the other hand, reduce the sharpness of the optimum, so that the peak of the curve is less pronounced. In yet other cases the catalyst may give rise to a vulcanised rubber with an abnormal extensibility relative to its coefficient of vulcanisation. Most of them, but not all, by reducing the time of heating necessary, cause the production of a rubber with a higher tensile strength than would be obtained by more tardy vulcanisation at the same temperature without the catalyst, and in this direction reduction of the time of vulcanisation by using an increased percentage of sulphur can have a similar effect (van Rossem, *loc. cit.*, p. 210).

The effectiveness of one of the above-named organic catalysts, *viz.*, aldehyde-ammonia, is demonstrated by the accompanying curves (Figs. 2-6) representing the results of experiments made, like those given in the earlier curves, with a mixture of pale crêpe and sulphur (90:10), at various temperatures from 148° C. (51 lb. steam pressure) downwards, in an oil bath vulcaniser. Even at a concentration of 1% the effect is still clearly observable while, with 1%, vulcanisation occurs so readily as to be possible in a reasonable period at 108° C., or less than 5 lb. steam pressure; Fig. 7,

indeed, records the progress of vulcanisation at 98° C. It will be seen that the temperature coefficient calculated by the ratio of the speed of reaction at intervals of 10° C. from 108° to 118° is practically the same as for the reaction in the absence of an artificial catalyst (p. 125 T), the average value for the accelerated mixings represented in Figs. 2-6 being 2.4. This observation militates against the belief of some investigators in this field that vulcanisation catalysts are not themselves able to expedite vulcanisation, but that during the early stages of the process they combine with sulphur, giving rise to substances which possess the desired activity. This view may be correct in certain cases, but evidently cannot be accepted generally for all vulcanisation catalysts. The average values of the coefficient with the various proportions of accelerator are given in the table:—

Average Temperature Coefficient.

Proportion of accelerator,	1% (108° - 148° C.)	3% (118° - 148° C.)	1% (118° - 148° C.)	1% (118° - 148° C.)	Nd (128° - 168° C.)
Method of testing—					
(a) Combination with sulphur ..	2.4	2.3	2.4	2.3	2.3
(b) Elongation at 0.5 kilo. per sq. mm. ..	2.5	2.5	2.5	2.4	2.3
(c) Maximum tensile strength ..	2.5	2.5	2.2	2.5	2.4

It is a striking fact that although the individual values of the temperature coefficient between 108° and 148° C. without exception oscillate closely about the mean value of 2.4, the interval 98°-108° C. shows a much greater value exceeding 5.0. This is doubtless due to the melting of the sulphur between these two latter temperatures, the normal melting point being lowered under the obtaining conditions. This observation supplies a confirmation of the argument on page 125 T as to the comparable effectiveness of the various allotropic forms.

The fact observed above, that the temperature coefficient possesses comparable values for mixings with and without an artificial catalyst, appears from other results in our possession to be a general one for all catalysts. This facilitates the representation of the relative effectiveness of different catalysts by means of a numerical factor. A factor representing the ratio of the respective periods of vulcanisation required for the attainment of a definite state of vulcanisation in a rubber-sulphur mixing, with and without a definite proportion of accelerator, will be independent of the temperature; it will be essential that this comparison be made at a stage of the vulcanisation process when the mixture still contains a considerable proportion of uncombined sulphur. The resulting "acceleration factor" may differ according to which of the three possible criteria—percentage of combined sulphur, maximum tensile strength and extensibility at definite load—is taken as fixing a definite state of vulcanisation. In the case of the accelerator used in the experiments now quoted, the behaviour may be described as normal, all three methods giving comparable results. The effectiveness calculated in this way for the accelerator at various concentrations and at different temperatures is given in the following table; the figures in each case represent the mean of the values obtained by the three different methods for the comparison of rate of vulcanisation.

Stated otherwise, the presence of 2, 4, 1, and 1% respectively of the accelerator increases the rate of vulcanisation at any ordinary vulcanising temperature to 1.7, 3, 5, and 7½ times the normal. A

* This does not refer to the so-called "technical optimum" of vulcanisation for which the corresponding coefficient of vulcanisation in the presence of a catalyst may fall as low as 2 or 1. (Kratz and Flower, J. Ind. Eng. Chem., 1919, 11, 39.) The technical optimum cure is probably capable of less definite measurement than the maximum tensile strength in the type of mixing used above.

"Acceleration factor."

Percentage	1	2	3	4
Temperature—				
118°–128° C.	1.7	2.8	5.1	7.5
128°–138° C.	1.7	3.0	5.4	7.6
138°–148° C.	1.7	3.0	4.8	7.1

Fig. 8.

Fig. 8. The slight divergency (from the course of the smooth curve) of the points for the lower percentages is doubtless due to the relatively greater effect of the inevitable small loss of accelerator by vaporisation during the mixing operation.

Fig. 9 includes curves showing the relative effectiveness of isomeric substances, viz., *m*- and *p*-phenylenediamine as accelerators. The meta-compound is notably less active than its para-isomeride. It is of interest to note that the effectiveness of these two substances towards vulcanisation falls in the same order as their affinity constants as determined by Bredig in 1891. The low value of the coefficient of vulcanisation at the maximum tensile strength of the *p*-phenylenediamine mixing will also be noticed. The absence of points on the extensibility curve beyond a coefficient of 4 is due to the samples concerned being over-vulcanised and too weak for the test.

In Fig. 10 are given the results of tests on four different occasions and with three separate mixings, containing 1% of *m*-phenylenediamine; they are of importance, particularly in the extensibility section, as demonstrating the comparableness of figures obtained, even in independent experiments, with the standardised conditions adopted in this investigation.* The "acceleration factor" for *m*-phenylenediamine, calculated from the results in Fig. 8 has a mean value of approximately 1.5; for *p*-phenylenediamine judged by the physical methods the factor is approximately 3.3, whereas the rate of combination with sulphur indicates a value of only 3.0.

Fig. 11.

Fig. 12.

Mixed Catalysts.

The effectiveness of a mixture of catalysts in an ordinary chemical reaction is well known not to coincide invariably with the sum of the effects produced by each independently. This peculiarity is also observable with vulcanisation catalysts (Dittmar, *Gummi-Zeit.*, 1915, 29, 424). Lead oxide with magnesium oxide, and *p*-nitrosodimethylaniline with aniline or one of its homologues, are cases which have already been quoted in the literature.

Fig. 10.

A related phenomenon probably is also the power of zinc oxide, which alone does not accelerate vulcanisation, to increase considerably the effectiveness of other organic catalysts such as hexamethylenetetramine and thiocarbonyl (see Figs. 11 and 12). As the latter by itself is practically inert, we have the interesting case of a mixture of two inactive substances exerting a distinct accelerating effect. In other cases we have found two vulcanisation catalysts to be "incompatible" in the sense that the effectiveness of the more active catalyst is actually decreased by the presence of the other.

As has been intimated already, no acceptable general explanation is yet possible as to the mode of action of vulcanisation catalysts. In addition to the theories already mentioned, others have also been proposed. An observation of considerable interest in this connection is that rubber in solution or wetted with benzene becomes vulcanised by successive treatment with sulphur dioxide and hydrogen sulphide at the ordinary temperature (Peachey, *this J.*, 1919, 688A). This reaction appears to be very suggestive in connection with the action of vulcanisation catalysts. None of the three modifications, S_{λ} , S_{μ} , and S_{π} present in liquid sulphur appears to be in possession of exceptional chemical activity towards rubber (see above), but there is evidently a possibility that there is capable of existence yet another form of sulphur of much greater vulcanising power. Such a view, needing considerable modification however, has already been tendered (Dubosc, *India-rubber World*, 1918, 59, 78; 1919, 59, 248), but the scope for investigation in this direction is enormous; indeed, the evidence available as yet is insufficient even to exclude the possibility that vulcanisation accelerators may activate the rubber and not the sulphur.

We are pleased to acknowledge the valuable assistance of Mr. C. W. H. Howson, B.Sc., in connection with the experimental work recorded above, and our indebtedness to the Dunlop Rubber Co., in particular to Mr. J. V. Worthington, Technical Superintendent and Director, for permission to publish this paper.

Bristol and S. Wales Section.

Meeting held at Cardiff on March 3, 1920:

MR. W. S. BIRD IN THE CHAIR.

RESEARCHES ON COAL.†

Part II.—An investigation of certain coking coals:
A theory of coking.

BY S. ROY ILLINGWORTH, B.Sc., F.I.C., A.R.C.S.

The various theories that have been advanced from time to time to explain the phenomena accompanying the production of coke from coal are reviewed by V. B. Lewes in Chapter 8 of "The Carbonisation of Coal" (1912). The author states: "Most observers look upon the luting body in the coal as tar residues." Wedding differs from this view and attributes the production of coke to the deposition of carbon within the mass of coal by virtue of the destruction of gaseous hydrocarbons. Donath and others consider that the production of a coke is due to internal change in the nature of the carbon molecule. Lewes advanced the opinion that the formation of coke arises from the successive deposition and decomposition of the heavy tars from layer to layer of the charge. The distillation of the heavy tars and their subsequent decomposition is due to the gradual flow of heat from the hot oven walls into the charge. Anderson (this J., 1898, 1027) ascribes the coking qualities of a coal to the presence in the coal substance of resinic bodies, and from the different behaviour of certain Scotch coals under the action of caustic soda, together with the different stabilities of these coals at 300° C., he divides the resins into two classes:—(a) One class decomposed below 300° C. and saponified or oxidised by caustic soda; (b) a class stable above 300° C. and not altered by caustic soda. Wheeler and Stopes in their "Monograph on the Chemistry of Coal," p. 9, make the following comment on Anderson's work:—"The compounds extractable by alkali solutions are undoubtedly ulmin compounds . . . moreover their presence in coals has been shown to exert a detrimental effect on the coking properties of the coal." Anderson's views must therefore be considered as not based upon conclusive evidence as to the nature and properties of the resinic substances in coal. Finally, Bedson, in 1900, showed that the cementing principle in certain coals was capable of extraction by pyridine, a view that was subsequently enlarged by Wheeler when he showed that the pyridine-soluble portion of a coal could be separated by extraction with chloroform or benzene into two portions, only one portion of which—the resinic or gamma compound—was possessed of coking qualities. Any endeavour to formulate a theory of coking must not solely take into account the mere formation of a coke, but in addition some light must be shed on the variations of strength, porosity, etc., of the cokes from different types of coals.

The differences in behaviour of the four coals dealt with in the first part of this paper (J., 1920, 1117) cast considerable light upon the fundamental causes influencing the nature of the cokes resulting from various coals.

The coal substance can be split into three types of substance by the "pyridine-chloroform" method of extraction. In conformity with the observations of Wheeler, Bedson, and others it was observed that

only the resinic constituents of the coals examined left a coherent residue when carbonised at temperatures varying from 450° to 900° C. Tests with mixtures of any two of the three components of the coals proved that only those mixtures containing resinic substances were capable of giving a residue of a coherent nature at 900° C. Consequently the property of causing the cohesion of a coal into a coke on carbonisation must be ascribed solely to the resinic portions.

The investigation of the decomposition of the coals at 450° C. proves that under the continued influence of this temperature a progressive destruction of the resinic portion of the coal substance results in the production of residues containing decreasing quantities of this type of substance. The residues obtained were ground to the same degree of fineness, and 1 grm. was heated at 900° C. under standard conditions in order to determine if a residue were formed which failed to produce a coke. The minimum amount of resinic substances necessary for the production of coke must lie between the amount present in that residue which produced by the shortest period of heating fails to yield a coke, and the residue anterior to it in series which does coke.

TABLE XXIII.

The coking properties and percentage volatile of residues from the various coals.

Residue.	Temp. of formation.	Volatile 950° on residue.	Resinic subs. in residue.	Nature of coke.
No. 2 Llantwit.				
1½	450	35.10	7.56	Dense hard coke.
1½	450	24.30	7.37	do.
3½	450	24.00	—	Very weak coke; scarcely coked; much detritus.
5½	450	24.10	5.33	do.
9½	450	23.20	5.63	do.
24½	450	21.00	4.00	No coke.
4½	350	32.00	—	Dense hard coke.
10½	350	30.85	0.30	do.
10½	400	—	—	No coke.
No. 3 Rhondda.				
1½	450	21.63	9.86	Dense hard coke.
3½	450	21.70	7.58	do.
5½	450	21.65	5.30	Dense coke.
24½	450	19.40	5.73	Coked; a little detritus.
No. 2 Rhondda.				
1½	450	20.51	7.99	Dense coke.
2½	450	14.56	5.01	Coked; much detritus.
5½	450	12.08	3.12	No coke.
12½	450	11.49	2.60	do.
Two foot nine.				
1½	450	19.18	8.62	Dense hard coke.
2½	450	16.70	6.36	do.
5½	450	16.10	4.51	Coked; much detritus.
24½	450	14.82	1.12	No coke.

The above results indicate a difference in the cementing properties of the various resinic substances in the different coals; those in the No. 2 Llantwit have a weaker coke-producing quality than the others. The minimum amount of resinic substances in the residues from the various coals necessary to yield a coke lies between the following limits:—For the No. 2 Llantwit, 6–7%; No. 3 Rhondda, 5.30; No. 2 Rhondda, 5.0–5.5%; Two Foot Nine, 4.5–6.36%. The mean figure for the majority of the coals is about 5.5%, but probably for those coals containing less than 84% of carbon in the coal substance this figure will tend to increase. The investigation detailed in Part I. has led to the formulation of a new theory of coking, which will be first enunciated, and subsequently the facts upon which it is based will be indicated. It has been there shown that every coking coal is characterised by a fairly well-marked temperature

† Part I. of this investigation was published in the May 15th, 1920, issue of this Journal, p. 1117.

at which coking commences. The view is held, in agreement with Anderson, that all coking coals soften and become plastic, but this temperature is regarded as not far removed from 400° C. The β -cellulosic constituent of the coals examined by Wheeler (*J. Chem. Soc.*, 19—, —, —) were devoid of any tendency to melt or soften, but he found that the resinic substances melted at 150° C. Observations on the coals examined in the present research reveal the same characteristics of the two cellulosic types of substance, and confirm the fact that the resinic substances readily melt at 200° C., and become practically fluid at 350° C. in an inert atmosphere. The plasticity of the coal is therefore attributed to the liquation of the resins by heat, and the subsequent flow of the fluid or semi-fluid resinic matter around the other solid ingredients of the coal; possibly a definite absorption of the liquid resins by the other solid constituents takes place. The degree of plasticity in a coal is conditioned by the following factors: (a) the amount of resinic matter present; (b) the melting point and the point of complete fluidity of the resinic constituents; (c) the temperature to which the coal is subjected; and (d) the proximity of that temperature to the point of decomposition of the resinic constituents. The greater the amount of resinic substance present the more plastic the coal will become; too great an amount of resinic substance will result in a "molten" coal capable of flowing like a liquid. The initial cementation into a coke of the residues arising from the destruction of the constituents of a coal is due to the skeleton of carbon deposited between the non-melting ingredient by decomposition of the resinic substances.

The process of coking consists of the decomposition of the various substance in the coal with the evolution of volatile matter and the formation of a very highly carbonaceous residue. The decomposition must take place in the order of the thermal stability of the substances in the coal, for (in the modern type of coke oven) a very gradual temperature gradient exists between the hot walls of the containing vessel and the centre of the charge. The curves in Fig. 8 are constructed from the measurements of the temperature at various places in a coke oven, made by Simmersbach and detailed on page 335 of the first edition (1916) of Wagner's "Coal and Coke."

Fig. 8.
Temperature of coal in coke oven.

No doubt during certain intervals of time several substances are simultaneously undergoing decomposition, due to the temperature gradient in the oven increasing at a more rapid rate than permits of fractional decomposition of the coal substance.

The early stages in the carbonisation of a coal comprise, as the above results have shown, the destruction of the resinic and β -cellulosic substances, and consequently that phase of carbonisation taking place at temperatures below say 500° C. is the phase concerned with destruction of plasticity in the hot mass of coal. As a generalisation 5.5% is the minimum amount of resinic matter necessary (in a coal) for the formation of a coke, and since the passage through various degrees of plasticity is a characteristic feature of coking coals under the influence of heat, 5.5% of resinic substance may be taken as the minimum amount necessary to render a coal mass plastic. Throughout the period that a coal undergoing decomposition contains above 5.5% of resins the resulting plastic mass will tend to be forced into a spongy state by the internal pressure resulting from the generation within the mass of gaseous and other products volatile at the existing temperature. The progressive destruction of the resinic substances results in a change of the hot coal from the state of initial maximum "fluidity" through increasing degrees of "viscosity," the approach to a very viscous or semi-solid state, and finally the absence of any plastic nature due to the reduction of the resinic content of the mass below 5.5% of the residue. When the plastic mass is most fluid the volatile matter evolved will tend to pass through the mass and escape from it without forcing it into a spongy state, but as the whole becomes more viscous the volatile matter will tend to be retained within the mass as isolated bubbles, and will force the semi-coke into a spongy form. There must ultimately arise a state of affairs approximating to the stage at which the resinic substance in the residue has been reduced to some 5% or 6%, under which the volatile matter is generating within a medium so viscous that it takes a very appreciable period for that portion capable of escaping against the resistance of the mass to escape. The next phase is the loss of plasticity in the mass due to the further destruction of the resinic substances. It can readily be appreciated that the structure of the coke will be fixed since the final production of the carbon skeleton binding the mass into a rigid body has now taken place. Vesicles or pores will thus be formed in the coke, and their size will be conditioned by the pressure exerted by each occluded pocket of gaseous matter on the semi-solid mass just prior to it losing the final low degree of plasticity. The fundamental consideration determining the degree of porosity of a coke according to the theory here advanced is first the number of gaseous bubbles occluded in the coal mass when the resinic content is in the neighbourhood of 5.5%, and secondly the pressure exerted by the gaseous matter thus occluded. These two factors are both determined by the amount of volatile matter evolved from the coal substance in that period just prior to the decrease of the resinic matter to below 5.5%. The volatile matter evolved in the early periods is of lesser importance as regards its influence on the porosity of the coke, since so long as the mass is decidedly plastic it can "rise and fall" with any fluctuations in the evolution of gaseous substance; moreover, even if the volatile matter should force the coal into a spongy state, such a mass would sink down as soon as the evolution of volatile matter had decreased. It is not suggested that a coal becomes actually fluid during carbonisation. The terminology of plasticity etc. adopted above must be taken more as an analogy than as a dogmatic statement of physical state. The successive stages indicated are not visualised as ensuing throughout the whole mass of the charge at the same time, but as a cycle of events taking place from layer to layer of the charge in a direction parallel to the hot walls of the oven and conditioned by the rate of penetration of heat towards the centre of the charge. The fact that considerable pressure must exist within a coke

is evident from the following figures due to J. Parry and quoted by Lewes ("The Carbonisation of Coal," 1912, p. 221):—20 grms. of a coke of the following composition: C, 89.45; H, trace; O+N, 1.305; S, 0.795; ash, 8.45 %, gave rise to 361.5 c.c. of gas after heating for 2½ hours, and all told yielded 1117.2 c.c. after 14½ hours' heating. The gas evolved in the first 2½ hours contained CO, 22.8; CO, 13.4; H, 50.0; CH₄, 13.8 % by vol. The presence of methane in this gas is evidence of the occlusion of gases evolved at temperatures below 700° C., for Burgess and Wheeler (J. Chem. Soc., 1910, 97, 1917) state that paraffins cease to be produced above this temperature. The volatile matter evolved from a coal during any period of time at temperatures below 500° C. is the sum of the volatile matter arising from the resinic and β -cellulosic components undergoing decomposition. The resinic constituents are the source of the substance which cements the various residues from the coal substance into a coherent coke; associated with the formation of the "cement" is the evolution of a definite amount of volatile matter derived from the resinic substances undergoing degradation to carbon. This volatile matter *per se* must result in the production of porosity in the coke, the degree of which is determined by the amount of volatile matter evolved in the period just prior to the destruction of coking qualities in the layer of coal considered during the period of time when the resinic content of the semi-carbonised mass is between 5 and 6%.

Some indication of the difference in the amount of volatile matter evolved at various temperatures from the resins in certain of the coals examined is evident from the following table, the values in which were determined by heating 1 gram. of the resin at the specified temperature for seven minutes in a platinum crucible:—

TABLE XXIV.

Percentage of resins volatile at various temperatures.

Coal.	425° C.	600° C.	950° C.
No. 2 Llantwit	29.43	60.03	81.04
No. 3 Rhondda	8.9	56.00	69.45
No. 2 Rhondda	12.87	54.60	64.21

The marked difference in volatility of the resinic constituents of the No. 2 Llantwit (and the No. 2 Rhondda) is very evident; it constitutes a characteristic difference in property of the resins in the gas and coking coals. This greater volatility at the lower temperature in conjunction with the fact that of the coals examined the No. 2 Llantwit is the only one to decompose (to any great extent) at 350° offers some explanation of the greater porosity of the coke from this coal, but other factors have yet to be considered. The previous results have shown that the true coking coals contain an apparently homogeneous β -cellulosic constituent which is decidedly more unstable than the resinic constituents in these coals, and is practically destroyed in the first three hours of carbonisation at 450° C. On the other hand, the gas coals contain a β -cellulosic substance of the same order of stability as their resinic constituents, and it is associated to a considerable extent with the residual resinic remaining in the coal after long periods of carbonisation at 450° C. The true coking coals lose their β -cellulosic constituents as such in the very early periods of coking when the coal is still possessed of considerable plasticity, and the volatile matter arising from the decomposition of this type of substance is largely able to escape from the mass. The result is that during the critical period of carbonisation the viscous coal mass is only under the leavening influence of the volatile matter evolved from the resinic

substance, an amount much smaller than that evolved from the resinic substance of the gas coal, hence the texture in the case of the coking coal is more compact than that arising under similar conditions from the gas coals. Due to the greater stability of the β -cellulose in the gas coals and to its resultant association with the resinic matter throughout long periods of carbonisation at 450° C., the coal mass of the gas type of coal is, during the critical period, not only under a greater leavening influence arising from the greater amount of volatile matter evolved from the resins themselves, but added to this must be the effect of the volatile matter evolved from the β -cellulosic substance remaining in the semi-coke and undergoing decomposition concurrently with the resinic substances. The greater stability of the β -cellulosic substance and high yield of volatile matter from the resinic substance are among the chief causes of the porosity of the cokes from the gas type of coals.

Fig. 9.

Fig. 9, showing the variation of the ratio of resinic to β -cellulosic constituents in the various residues derived from the coals investigated, illustrates the rapid rise towards the maximum of these curves for the true coking coals compared to the very slow rise of the curves for the gas coal—facts due to the greater relative stability of the β -cellulose in the latter type of coal.

TABLE XXV.

Percentage of β -cellulosic constituents volatile at various temperatures.

Coal.	425° C.	600° C.	950° C.
No. 2 Llantwit	14.01	20.83	37.45
No. 3 Rhondda	10.08	22.16	27.01
No. 2 Rhondda	9.42	14.81	28.69

The results in the above table were obtained in the same manner as the results given in Table XXIV. The greater amount of "volatile" evolved at the lower temperature in the case of No. 2 Llantwit is a feature that still further increases the tendency of this coal to produce a porous coke. The volatile matter evolved during any interval of time by decomposition of resinic and β -cellulosic material in the coal is actually the volatile matter evolved from that portion of the coal substance soluble in

pyridine and decomposed in the interval of time considered. This figure can be determined, since it is the loss of weight of the coal substance for any period divided by the decrease of pyridine-soluble constituents in that period. The loss of weight of the coal substance of the various coals in any given period is readily obtained from the data detailed in Table VII., whilst the corresponding amount of pyridine-soluble substance destroyed can be obtained from Tables VIII., XI., XIV. and XVII. The percentage ratio figures thus obtained are for brevity termed the "period volatile."

Fig. 10.

Fig. 11.

The loss of weight and the loss of pyridine-soluble substance per hour per 100 grms. of coal substance are represented for each coal in figs. 10-13. From these results the ratio curves have been constructed. It is readily apparent that the order of the coals as regards the amount of volatile matter yielded at any instant by the decomposition of the pyridine-soluble substance is as follows:—No. 3 Rhondda, No. 2 Llantwit, No. 2 Rhondda, Two Foot Nine

Seam. In the case of the coking coals the curves reach a maximum value in the early period of heating and fall rapidly towards a minimum. The crucial characteristic of any coal as regards porosity

Fig. 12.

Fig. 13.

of the resulting coke is the amount of volatile matter evolved when the hot mass is in its most viscous state and about to pass to a fixed structure by virtue of destruction of the resinic. In the case

of No. 2 Llantwit this change occurs between 3½ and 5 hours' heating at 450° C.—in all probability at the end of 4 hours' heating. At this time the volatility of the pyridine-soluble substances undergoing decomposition approaches the maximum, and hence the viscous mass just prior to fixation of form is under the influence of the maximum leavening effect that arises from this coal. The destruction of coking qualities in the Two Foot Nine and No. 2 Rhondda occurs after 4½ and 2½ hours' heating at 450° C. respectively, at which time the percentage of the volatile matter evolved from the pyridine-soluble substance undergoing change is far removed from the maximum value and approximating towards the minimum value. Hence the leavening influence in this type of coal is comparatively small.

The leavening effect during the critical stages is the total volatile matter evolved during this period, the value of which from 100 parts of coal substance can be calculated by multiplying the amount of pyridine-soluble substance undergoing decomposition by the percentage volatile of the substances decomposed. The values for the various coals at their critical period are given in the following table:—

TABLE XXVI.

Leavening effect based on 100 parts of coal substance at critical periods.

Coal.	Loss wt. per hour.	% volatile from pyridine-soluble.	Total volatile per hour (porosity factor).
No. 2 Llantwit ..	1.0	73	0.73
No. 2 Rhondda ..	1.8	18	0.32
Two Foot Nine ..	1.9	8	0.16
No. 3 Rhondda ..	0.2	45	0.09

The figures in column 3 of the above table are termed the "porosity factor," and it is interesting to note that the numerical values of the factors for the individual coals are in the same order as the porosity of the cokes they give rise to.

No. 3 Rhondda is intermediate in nature between the gas and coking coals. On an industrial scale it is utilised for both purposes. In many of the features so far discussed for the several coals this particular coal has behaved more like the gas coals than the coking coals, but it will now be shown that No. 3 Rhondda has all the special characteristics of a true coking coal. The data given in Table XXIII. show that after 24 hours' heating at 450° C. the coking qualities of this coal are not destroyed. The curves in fig. 5 indicate the greater relative stability of the pyridine-soluble constituents of this coal. In addition the general curvature of the curves in fig. 3 leads to the conclusion that the β -cellulosic constituents will be wholly destroyed at the end of 48 hours' heating at 450° C.; at the expiration of this time there will remain in the residue some 5–6% of resinic matter, an amount sufficient to cause the residue to coke. The critical period in the production of a coke occurs after a long lapse of time, and it is evident from the extrapolated results derived from the curves in fig. 12 that during the critical phase the pyridine-soluble constituents will be undergoing decomposition at a rate not exceeding the destruction of 0.2 grm. per 100 grms. of coal substance, and that the volatile figure of the constituents destroyed will be 45% by weight.

The porosity factor will thus have a value 0.1, which is lower than that of any of the coals considered, and hence the coke from this coal will be of a dense nature. The very low rate of decomposition of the resins in the coal coupled with the resulting longer periods of time that the hot mass is in a plastic state allows the volatile matter

evolved to escape from the mass, and it is this long period of coke formation which nullifies the highly volatile nature of this coal and its propensity to result in a porous coke.

The theory of the causes of porosity in a coke is thus developed from experimental data. In photomicrographs taken by direct illumination of the surface of the residues of No. 2 Llantwit coal, the large vesicles and stream lines of the molten resins are evident in the one-hour and two-hour residues. The 5-hour and 24-hour residues are devoid of large vesicles, individual particles of the charge are not evident, and the whole mass has settled down to a compact coke.

Hardness of coke.

The hardness of a coke is determined by two factors: (a) The total amount of cementing material in the coke; (b) the distension of the cementing material, i.e., the volume over which it is dispersed, a factor conditioned by the porosity of the coke produced.

The initial cementing material in a coke results from the amount of fixed carbon left after decomposition of the resinic substance. The total hardening or cementing material is the initial material plus that amount of carbon subsequently deposited by the degradation of hydrocarbons etc. at higher temperatures—say above 600° C. Work is at present proceeding in order to ascertain the maximum amount of resinic substance from the coals discussed. Meanwhile the maximum amount so far obtained is taken as a basis for calculating the initial cementing materials in the coals. This figure is obtained by multiplying the percentage of resinic substances present by the amount of fixed carbon they yield when carbonised; the results are detailed in Table XXVII.

TABLE XXVII.

Coal.	Resin-ic matter	Fixed carbon.			Carbon per 100 coal substance.		
		425° C.	600° C.	950° C.	425° C.	600° C.	950° C.
No. 2 Llantwit	9.65	70.57	38.97	18.96	6.81	3.76	1.83
No. 3 Rhondda	14.07	91.10	44.00	30.55	12.81	6.19	4.30
No. 2 Rhondda	10.18	87.13	49.54	35.79	8.89	5.04	3.64

It is evident that the gas coals give rise to a smaller amount of initial cementing material at any temperature and must hence produce a coke of weaker mechanical properties than the other coals. The initial cementing material, in my opinion, is the main cause of the hardness of a coke, for the amount of oil left behind and non-volatile at 450° C. in the various residues arising at this temperature never exceeded 1% by weight of the coal. The figures given above indicate the reason for the brittleness of low-temperature cokes due to incomplete carbonisation of the resin. The thermal stability of the resinic substances influences the hardness, since a very gradual decomposition of these substances may result in the small amount of fixed carbon produced at one instant being disrupted by a rise in a semi-coked mass at a subsequent period. On the other hand, a rapid decomposition of resinic substance means a rapid fixation of structure and will per interval of time produce more fixed carbon, a stronger structure and one least liable to fracture by internal pressures arising during any subsequent interval.

The brittleness of certain batches of coke from the No. 3 Rhondda is to be ascribed to the periodical rising and falling of the semi-coked mass resulting in the alternate formation and partial fracture of structure, a sequence of events very possible since this coal contains a remarkably stable resinic substance and the "period volatile" of the pyridine-

soluble constituents reaches a very high figure by comparison with the other coking coals. It is interesting to compare the views here developed with the phenomena arising in actual practice. This aspect of the question will be developed at length in another communication; it will suffice for the moment to recall that the gases resulting in the very early stages of carbonisation are weak gases poor in hydrocarbons and comparable with the gas obtained by Wheeler by distillation of β -cellulose.

The endeavour in actual practice to shorten the period of coking in ovens by increasing the temperature of the oven walls often results in the production of a porous coke from a coal which under normal conditions yields a good furnace coke. The higher temperature of the walls results in a steeper time-temperature gradient in the oven and a considerable shortening of the time during which the charge is under the influence of temperatures below 500° C. The relative stability of the β -cellulosic and resinic substances will be the less differentiated the higher the temperature to which these substances are subjected; moreover, the critical period of the charge will be shortened by the higher temperatures. The result with higher flue temperatures will be that the fixation of structure in the coke will ensue nearer to the period of the maximum "period volatile" of the pyridine-soluble substances, a fact which will tend to produce a more porous coke.

Finally, it may be mentioned that, arising out of this series of researches, new processes have arisen that give every promise of bringing about the coking of coals at present unsuitable for production of metallurgical coke, improving the qualities of certain types of coal which yield inferior cokes under modern procedure, and thus materially enlarging our present gradually decreasing supply of coking coals—a class of coal so essential to the iron and steel industry. The processes have developed to the stage of large-scale trials, and they have been provisionally protected. I hope shortly to deal with this aspect of the question.

This investigation has been carried out in the Chemical Department of the South Wales and Monmouthshire School of Mines, Treforest. I desire to tender my best thanks to the members of the Board of the School for the facilities so kindly provided, and to Principal Knox and Mr. Robert Metcalfe for their interest and assistance throughout the work.

This work is being extended both in the direction of submitting the coals here considered to the influence of higher temperatures and the examination of a greater number of coals along the lines indicated.

Chemical Engineering Group.

Conference held at Newcastle-on-Tyne on December 15, 1919.

(Abstracts of Papers.)

HANDLING OF PETROLEUM IN BULK AT THAMES HAVEN.

BY N. A. ANFILOGOFF, F.I.C., M.I.MECH.E.

The Petroleum Storage Wharf at Thames Haven has a tank with a capacity of over 500,000 tons. The tank steamer is taken alongside any one of the four deep-water piers, and there empties its cargo by means of its own pumps through various pipe lines into the storage tanks on the wharf.

For high-flash petroleum the ship's pumps are

supplied with steam generated on board ship, while for discharging low-flash petrol or crude oils steam is supplied from shore. The steam is supplied by high-pressure boilers situated 800–1000 ft. from the ship and provided with superheaters, calculated to give sufficient superheat to insure the steam arriving at the tanker's pump cylinder at a temperature not less than that of saturated steam of that pressure. In practice it has been found that steam with 160 lb. gage pressure and a superheat of 140° F. travelled through a 3-in. main a distance of 850 ft., and at the end there was registered a temperature of 378° F., i.e., still showing some 20° F. superheat above the temperature of saturated steam. The loss of superheat worked out at about 1° F. for every 7 ft. of main.

When the cargo is discharged into the storage tanks of the ocean dépôt or installation the various products, in addition to those obtained from refining operations, have to be transported either direct to consumers or to inland or smaller dépôts for distribution. This is carried out by means of the ubiquitous square petrol can, by wood or galvanised steel barrels and drums, by either horse-drawn or self-propelled road tank car, by rail tank car, by towed bulk tank barges, or by small coasting tank steamers. At Thames Haven during 1918 the average daily handling of petroleum in bulk amounted to more than 2500 tons (750,000 galls.).

The works being spread over an area of nearly 200 acres, decentralisation had to be adopted rather than centralised power plant, and the 26 large B. & W. and Lancashire boilers are divided amongst eight boiler houses. A pumping installation is in close proximity to each boiler-house, the pumps employed being direct driven steam pumps of either the single cylinder or the duplex type. No type of pump will give equally good service with all grades of petroleum products under all and any conditions.

The duplex pump, used for limpid or non-viscous petroleum products, is of the usual "Worthington" pattern, where two steam cylinders side by side have pistons connected directly to two pump plungers. A D-valve is employed and the engine works without expansion. In the tandem, compound type of duplex high-duty pumps the steam is used expansively through high-pressure and low-pressure cylinders, and again each engine works its neighbour's valves. Some makers have fixed a Meyer type cut-off valve gear, which enables the engine to work without expansion for a certain predetermined part of its strokes and expansively for the remainder.

The general rules and details to be observed are that: (1) The pump rods, cylinder liners, piston rings (packing rings), valves guards, and springs should be of brass or gunmetal. (2) Valves guards, springs, and valve seats should be accessible. (A solid valve seat plate is preferable to separately screwed-in or pinned-in valve seats.) (3) Valve guards should be of ample strength to withstand the constant jar and should be pinned in addition to being screwed into valve seat. (4) Snuff or pet cocks should be provided both above and below delivery valve plate; and (5) the valve lift should be ample; if multiple valves are used the sum of the valve areas should be at least 25% greater than the area of the suction pipe. These pumps are recommended for such liquids as petrol, kerosene, and gas oils. Of two pumps capable of delivering the same quantity, the pump with the longest stroke (and fewer in number per minute) is to be preferred.

As in pumping petrol, for instance, the pump gets "gassed," a delivery air vessel with relief cock should be provided with every pump. Where the oil is very "gassy," or where long suction pipes are employed, a suction air vessel (similar to a delivery air vessel) should be provided. In pump-

ing petrol, especially, it is desirable that the pipes and pumps should be of ample dimensions to convey the quantity required without undue pressure. The suction pipes, if long, should be preferably larger than the inlet to the pump to avoid friction. The best packing for glands is "metallic" packing.

The provision of filter gauzes on the suction side of a pump is an advantage, but they must be designed in duplicate boxes, where the change can be easily effected, and must provide at least 25% more unrestricted area than the suction pipe itself.

For pumping the heavier and more viscous oils the single-cylinder pump is used. These direct-acting steam pumps consist of a steam piston at one end of the piston-rod and a plunger at the other. The pumps occupy little space and have very few working parts. They have no external valve gear, and the steam cylinder is so constructed that all the steam is utilised for effective work on the piston. The side valve operation is arranged so that there are no minute steam passages and consists of a very simple valve mechanism which is entirely enclosed. They have the longest stroke obtainable with the least number of strokes per minute, and automatically slow down at the end of each stroke; the valve gear and steam ports are constructed so that the piston does not strike the cover when running at excessive speed.

In pumping viscous oils a simple calculation from piston speed and size of bore and stroke will not necessarily give the number of gallons the pump is capable of delivering, because so much depends upon the viscosity of the oil, the temperature at which it is being pumped, and also upon the friction in the pipes. At ordinary temperatures 1° F. will change the friction somewhere about 5%. At Thames Haven, working with viscous fuel oils, the velocity through an 8-in. pipe frequently exceeds 6 ft. per second. The difficulties of pumping viscous liquids are enhanced by the fact that even when the oil is heated before it is pumped, when long lengths of pipe lines are used for delivering, there are a series of velocities inside the pipe, the highest being in the centre and the lowest where the oil comes in contact with the pipe itself, so that the internal liquid friction is considerable.

It is practically impossible to deduce formulae to provide definite data from which to select the size of pump required.

In practice, for the more viscous oils, especially those of which the viscosities cannot be measured in Redwood's No. 2 viscometer at 32° F., or such oils which have a setting point of, say, 50° F. or less, the storage tank is provided with steam coils and is kept at such a temperature as will reduce the viscosity sufficient to enable the oil to be pumped (usually between 80° and 100° F.).

The pipe-lines are in some cases enclosed in wooden boxes, with the steam pipe running alongside, but it would seem to be preferable to have a steam pipe running inside the oil pipe with the steam inlet at the end furthest away from the pump, so that the steam enters at presumably the coolest part of the pipe, and travels in an opposite direction to the oil. To prevent leakage of steam into the oil, glands are provided to permit the steam pipe to expand freely without becoming distorted in the pipe line, and taper-thread sockets are used for the steam pipe.

In pumping viscous oils it is essential that the suction and delivery pipes be of ample proportions, that a suction air vessel be used, that where filter gauzes are employed the area of such gauzes be at least 100% greater than the area of the suction pipe, and that the pump preferably have the least possible number of valves. These valves should each be of the largest possible size, and the valve seats should be so constructed that the webs do not unnecessarily break up the stream.

GENERAL TYPES OF PUMPING MACHINERY FOR CHEMICAL WORKS.

BY J. H. WEST.

The handling of liquids in chemical works involves a large variety of problems, ranging from the lifting of water from deep wells, fire service and boiler feeding, to the handling of highly corrosive liquids and of very thick and viscous liquids. A great variety of apparatus is available for dealing with these problems.

In selecting a pump for a particular purpose, reliability should be the first consideration, even beyond first cost or efficiency. It is mistaken economy to work a pump at maximum rating, since this involves very great wear and tear. It is usually recommended to work pumps for boiler feeding at half the piston speed given for general service duty, and it is more economical to use only 70 or 80% of the maximum piston speed for the latter. A long-stroke pump is preferable to a short-stroke one, since the wear on most parts is dependent on the number of reversals.

The direct-acting steam pump is cheaper than the flywheel steam pump. In the duplex form of pump a very simple steam valve gear can be used, since the motion of one rod actuates the valve on the other cylinder. These pumps are not economical in steam, owing to the necessity for considerable clearance at the ends of the stroke to allow of cushioning, and the duplex pump, unless well designed, is apt not to work its full stroke on both cylinders.

A ram pump has the advantage over one of the bucket type in that any slip past the plunger is apparent at the stuffing boxes, whereas considerable slip past a bucket plunger may take place without being detected.

The belt-driven centrifugal pump is probably the lowest in first cost of all types of pump, and the efficiency is high for large quantities but only moderate for medium quantities, especially at high lifts, and distinctly low for small quantities. The necessity of priming centrifugal pumps before starting, unless the liquid is supplied from a higher level than the pump, is a disadvantage for chemical work in most cases, but the absence of valves, and the fact that the decrease in efficiency owing to wear is probably less than in the case of reciprocating pumps, especially with the open type impeller, is in their favour. Trouble at the stuffing boxes is often due to faulty packing. A centrifugal pump with only a single stuffing box, and that on the suction side, has many advantages for chemical work.

In the case of pumps for corrosive liquids the question of safety and reliability far outweighs that of first cost or efficiency, since the quantities to be handled are generally comparatively small.

The choice of suitable valves has much to do with the satisfactory working of pumps lifting chemical liquors, and the provision of efficient strainers of ample area on the suction pipes is of great assistance to the proper operation of the valves.

PUMPING EFFICIENCY.

The following table gives the yearly cost of power for pumping water at various rates against a head of thirty feet, assuming 4000 hrs. to be worked in the year, and the cost of one h.p. hr. to be 14d., which is equivalent to electric power delivered to a motor of 85% efficiency at 1.42d. per unit.

In order to have a basis of comparison between the efficiency of steam pumps and those driven by belt or motor, it is necessary to assume a figure for the steam which represents a horse-power-hour, and in what follows this figure is taken at 35 lb.

The efficiency of small pumps of all types is very low, owing to the small hydraulic mean radius of

the passages, and this is particularly marked with centrifugal pumps.

Gallons per hour.	Yearly cost of power in pounds at various efficiencies.							
	100%	70%	60%	50%	40%	30%	20%	10%
500	1.6	—	—	—	4.0	5.3	7.9	15.8
1,000	3.2	—	—	6.4	8.0	10.7	16.0	32.0
5,000	16.0	—	26.7	32.0	40	53.0	—	—
20,000	64	91.4	106.7	128	160	213	—	—
50,000	160	229	267	320	400	533	—	—

A 1-in. centrifugal pump throwing 1000 gallons per hour against a head of 30 ft. will have an efficiency of 15% to 18%, a 2-in. pump throwing 5000 gallons per hour will show about 40%, a 3-in. pump throwing 10,000 to 12,000 gallons 55% to 60%, while efficiencies of 70% and over are only attainable in pumps of 6-in. or 7-in. and over, handling 50,000 gallons per hour upwards.

For any given centrifugal pump there is a certain set of conditions as to speed, quantity, and head, for which the efficiency will be a maximum, and any deviation from these conditions will mean a decrease in efficiency. It is desirable, therefore, to some extent, to design every centrifugal pump for the particular conditions under which it is to work, in order to get the best results.

The efficiency of duplex steam pumps will vary from about 20% in small sizes up to 40% in large sizes, corresponding to steam consumptions of 175 lb. per h.p.hr. to 88lb. That of direct-acting pumps will range from 25% up to 50%.

The efficiency of flywheel pumps is usually several per cent. better than that of direct-acting pumps of the same capacity, owing to the smaller clearances in the steam cylinder and the greater ease in working expansively. The steam consumption can be reduced considerably by compounding the steam cylinders, and also by fitting condensers to the exhaust.

Where the exhaust steam from pumps can be used for heating liquors in chemical works, the steam consumption is of little consequence, since nearly 90% of the heat in the live steam is recovered in the exhaust steam.

The efficiency of diaphragm pumps ranges from about 14% in small sizes up to 20% in the largest sizes usually made.

TYPES OF PUMPS.

Pumps may be classified as follows:—

- (1) General service pumps, *viz.*, those for water and non-corrosive chemical liquors. This type includes reciprocating pumps and centrifugal pumps.
- (2) Pumps for gritty and thick viscous liquids. These may be of the reciprocating or rotary type.
- (3) Pumps for corrosive acids, of reciprocating or rotary types.
- (4) Pumps operated by compressed air. These include the well-known acid eggs, either plain or automatic, and the air-lifts.

In using the egg for liquids containing solids in suspension, it is a good plan to introduce the air through the perforated pipe at the bottom of the vessel, instead of at the top, to keep the liquid agitated and prevent an accumulation of solids.

The efficiency of eggs and automatic elevators is a subject upon which little or no information based on actual tests is available, and it will be of interest, therefore, to consider the overall efficiency of the system.

Take the case of an automatic elevator in which the compressed air is admitted by a float or other mechanism as soon as the liquid reaches a certain level in the egg. As soon as air is admitted, pressure begins to build up and the liquid begins to rise in the delivery pipe, going on until it begins to flow out from the discharge top of the pipe. The rate at which the air pressure builds up will depend upon the size of the air inlet, but the air space above the liquid being very small, it is safe to assume, unless a reducing valve or regulator is used, that in most cases it will reach the full pressure in the air main almost instantaneously and the column of liquid in the discharge pipe will have been accelerated up to the maximum velocity corresponding to the air pressure used by the time the liquid reaches the top of the discharge pipe. In any event equilibrium will very quickly be attained at a velocity such that the "static" head plus the friction head equals the air pressure.

For instance, if water is being blown through a straight vertical 3-in. cast iron pipe 60 ft. long, the static head is 26 lb. per sq. in. and if the air pressure were only 26 lb. per sq. in. it would just raise the water to the top of the discharge pipe without causing any delivery, while an additional air pressure will cause a flow at the following velocities:—

Air pressure in excess of 26 lb. per sq. in.	Velocity of flow ft. per sec.
0.3	2
1.1	4
4.3	8
15.6	16

Thus if the air supply is at a pressure of 40 lb. per sq. in. the water will flow out with a velocity of about 15 ft. per sec.

This condition of equilibrium will be maintained, provided the air supply pressure remains constant until the egg is empty, with the exception of a slight decrease in the static head owing to the lowering of the liquid level in the egg, the depth of liquid in the egg of course balancing a corresponding column in the discharge pipe.

In automatic elevators where the air supply valve is gradually closed by a float which falls with the liquid, a certain amount of wire-drawing takes place, and the final air pressure may not be greater than that required to discharge the liquid with a moderate velocity; in fact, in some elevators, such as the Kestner, a regulator is provided to ensure this, but in any event the minimum amount of air used will be equal to the volume of the egg at the supply pressure.

In the case of hand-operated eggs, under the best conditions where the workman stands with his hand on the air-control valve and his ear against the discharge pipe, he is able to shut off the air immediately he hears the last of the liquid leave the egg, and he probably uses no more air than an automatic elevator, but if the air is not shut off at the proper moment, the waste of air may be very considerable, as will also be the case if the egg is not completely filled with liquid.

In comparing hand-operated eggs with automatic elevators, it must be remembered that the former are usually much larger than the latter, being often of 500 up to several thousand gallons capacity, as against 3 to 20, or sometimes 100 gallons in the latter, and the advantage in air economy is all in favour of one big blow instead of numerous small ones.

There is no reason why automatic elevator mechanism should not be applied to large eggs, but actually it is not often done. On the other hand, where a more continuous supply is required,

as in the case of acid supply to towers, the use of small eggs operating frequently is necessary.

The discharge pipes from eggs and elevators should be as nearly vertical as possible, otherwise at the end of the blow the air may break through the column of liquid and escape along the upper side of the pipe. The clearance or air-space at the top of an egg or elevator must be reduced as far as possible, since it represents so much wasted air.

The efficiency of blow eggs decreases with increasing pressure, owing to the greater amount of energy contained in the air left in the egg at higher pressures.

The homogeneous lead lining of steel eggs affords a convenient protection against weak sulphuric acid etc. The use of ebomite lining for eggs has been adopted for hydrochloric acid.

The air-lift.—The air-lift provides an exceedingly simple method of raising liquids, and one that is fairly efficient if properly designed. It is not used in chemical works to anything like the extent it deserves. Compressed air is injected at the bottom of a discharge pipe so that alternate piston-like layers of air and water are formed in the pipe, thus lightening the column in the pipe and allowing the liquid to be blown out with an air pressure which may be as low as $\frac{1}{2}$ to $\frac{1}{4}$ lb. per foot of actual lift with water.

The use of air-lifts with hot liquids offers special advantages, since the heat energy of the liquid contributes to the work of pumping by expanding the air, and pumping efficiencies of 100% and over can be obtained in this way. Air-lifts are also used for lifting molten metals, and in such cases the thermal expansion of the air will be still more marked owing to the higher temperatures.

The correct proportioning of the "submergence," or ratio of the depth below the free level of the liquid in the well or feed tank at which the air is applied, to the total lift, has much to do with the efficiency of an air-lift, and while no hard and fast rules for determining this factor can be given, since it depends to some extent upon the size of the eduction pipe and the nature of the liquid, it is generally admitted that the lower the lift the greater should be the submergence, and that the greater the submergence the higher the efficiency. For lifts up to 100 ft. the submergence will usually lie between 50% and 70% of the lift, decreasing to about 35% with a lift of 500 ft. Efficiencies of over 30% can generally be obtained with a well-designed air-lift, and 40%, or even higher, can be reached in some cases with cold liquids.

In a method of applying compressed air in pumping known as "the return air system," reciprocating pumps of the steam driven type are used with compressed air instead of steam, and on the closed circuit system, i.e., the exhaust from the pumps returns to the compressor for re-use. In this method the economy in compression at the higher pressures is utilised, and losses of air through leakage are made up by the small booster compressor.

Steam ejectors are often useful for draining pits and sumps. Their low efficiency is against their use for other purposes.

The author described a large number of different types of pumps with illustrations, and also gave a number of general data on pumping.

THE MARCLEN PUMP.

BY R. A. STEWART.

This pump differs from other centrifugal pumps in being glandless. Essentially, it consists of a casing and a rotor or impeller with a vertical spindle. This method of construction has been adopted in order that glands may be dispensed with.

A belt-driven type of pump specially intended for sulphuric acid is shown in the accompanying figure.

The annular float, A, controls the admission of liquid through the inlet, C, and the annulus, L. The upper sloping part of the float seats itself on the corresponding sloping part of the annular part, which really constitutes a valve seating. The float moves freely in a vertical direction, but is not in contact with the spindle, as it is guided by the small ribs shown as upper extensions of the ribs, M. These ribs, M, of which there are four, form a rest for the float, and guide the liquid steadily into the eye of the impeller, F, which subjects it by centrifugal action to pressure in the chamber, G, whence it is forced through the outlet, H, into the delivery pipe. The impeller, F, is mounted on the spindle, D, which revolves in large bearings, K and O, the spaces between the bushes and main casting in each case forming grease reservoirs. The weight of the spindle and impeller is taken by a ball thrust bearing, N, which revolves in a covered grease chamber. All wearing parts are fitted with automatic grease lubricators. No parts liable to wear are exposed to the action of the acid. The body of the pump, J, the impellers, F and F', the sheathing of the spindle, E, the float valve, A, and annular inlet chamber, B, can be made of any suitable acid-resisting metal, stoneware, ebomite, or glass.

When working a full supply of acid is allowed to flow into the inlet, C, and, should this be too much, the float valve, A, rises and temporarily restricts the supply, but falls again when the level of the acid in the pump body becomes lower.

By a comparatively small modification of the design the pump is equally well adapted for raising other acids. For such purposes the pump may be made in ebomite, earthenware, or silicon-iron alloy, or even in stone. As a matter of fact these pumps have been working for over two years with various corrosive liquids, including concentrated and dilute sulphuric and phosphoric acids and hydro-

chloric acid. Also very strongly alkaline liquors, at the boiling temperature, containing a heavy sediment mixed with ashes.

The following are some of the uses for which this pump is well adapted:—The elevation of hot saline solutions to crystallising vessels; the removal of salts deposited from solutions undergoing evaporation; the emptying of caustic soda or sodium sulphide finishing pots; mixing liquids and solids in dissolving tanks—employed for this purpose the pump vigorously agitates the contents of a relatively very large vessel.

THE ELEVATION OF ACIDS BY THE KESTNER PATENT AUTOMATIC ELEVATOR.

BY J. A. REAVELL.

The use of the acid egg tends to great loss of air, and is generally inefficient. The Kestner

Fig. 1.

Fig. 2.

elevator was designed to overcome this waste and to do away with the labour required to operate the valves.

The standard elevator is shown in fig. 1, and the movements whereby the air is admitted and exhausted in fig. 2. Acid flows into the body of the elevator through the inlet valve which is coupled to a feed tank placed above it. As soon as the acid rises to a pre-determined height in the body, the float, X, operates. To obtain a quick action the float is carried into the narrow portion

Fig. 3.

of the top cover, and the acid flowing in rapidly fills this. The lever, C (fig. 2), works on the fulcrum, H, and the rod, K, which is coupled to the float, rises when the body is full. This at once releases the pressure from the air valve, R, and air is admitted into the head, passing down the standpipe into the body. At the same time, the pressure of the air closes the air exhaust valve, D. The compressed air blows the acid from the body up the delivery pipe to the receiving tank. A balance weight rod, F, provided with balance weights counterbalances the weight of the float.

As soon as the acid is blown out of the body, the float comes back to its original position and the exhaust valve opens at once, allowing the air to exhaust. The acid inlet valve then opens, and the cycle is repeated. The movement of the lever is very slight, the air valve having a travel of only about $\frac{1}{8}$ inch, so that the wear and tear is infinitesimal.

The stand-pipe should be of sufficient length so that the elevator head is above the level of the acid in the feed tank, thus preventing the flooding of the head with acid.

Fig. 4.

In a modification of this elevator, made of earthenware, for pumping nitric acid, the special feature is the method of connecting the float to the lever by means of a wire. Originally this wire was of platinum, but recently a special alloy has been used.

A continuous elevator has been designed for delivering acid into sprays, and for other purposes. This is shown in fig. 3. The lower portion consists of two bodies which may be made of cast iron lead lined, or unlined, as required, or of potware.

One of these bodies contains the float, which is operated by the valve shown in fig. 4. This consists of a taper plug type valve operating in a valve box, both of which are made of potware. The air is delivered into the head at H. The plug valve, R, is arranged with four ports which communicate with the openings marked 1 on the horizontal plane, and 2 on the vertical plane. As the float rises, owing to the inlet of the acid, the wheel, F, is rotated until the trigger, K, which operates in a slot in the wheel, comes in contact with the wheel. This then moves over B and causes the weight, E, to fall sharply, thus operating the valve, R, quickly. This operation turns on air to the cylinder that has just filled, and shuts it off from the cylinder that has just been emptied, exhausting this to atmosphere. There are two openings for each cylinder. For one cylinder the diagram shows these at 1 and 1A. Both these connect in a common pipe to the cylinder, 1B. If, for example, the valve has just operated on No. 1 cylinder due to it being full, then the compressed air enters through 1 into No. 1 cylinder and the exhaust from No. 2 cylinder leaves through pipe, 2B, by way of the valve, 2A, and vice versa—each cylinder filling and emptying alternately.

These elevators, which have been used for discharging acid through sprays at 40 to 60 lb. pressure on the sprays, are simple in operation and have no working parts revolving in acid, the only parts subject to the acid being the inlet and outlet acid valves. Some of them have been con-

tinuously in operation in chemical works for over fourteen years and the cost of upkeep amounts only to some few shillings a year.

CENTRIFUGAL PUMPS FOR SULPHURIC AND NITRIC ACIDS.

BY S. J. TUNGAY.

The centrifugal pump has many advantages over pumps of other types for lifting sulphuric acid. Their efficiency is high as compared with the use

Fig. 1.

Fig. 1 shows a 3-stage centrifugal pump again so arranged that there is but one stuffing box and

gland, with a thrust collar at the pressure side. This has been arranged with a by-pass leading to the first or suction chamber so that it is always subject to suction while working, and any leakage or overflow at this point is carried back to the suction side. This forms a very compact and highly

Fig. 2.

efficient design, the impellers being carefully balanced and internal friction reduced to a minimum.

Fig. 2 shows a single-stage vertical type centrifugal pump arranged for driving by vertical spindle, motor-coupled direct to pump shaft. The pump chamber has a bottom suction fitted with a balanced impeller, with a faced ring on the impeller working in a machined groove on the body in such a way that the gland packing has very little work to do. A ball bearing is arranged on the motor spindle and the pump works with but little internal friction. The multi-stage pumps are often arranged in the same manner.

A centrifugal pump which has been very successful for pumping nitric acid is shown in fig. 3. This pump is constructed entirely of acid-resisting iron, with the exception of the bed-plate. Arranged as

Fig. 3.

shown with an end suction, the impeller and spindle are in one piece. A long stuffing box and sleeve are adopted and oil grooves machined in the spindle and kept filled with ceresin wax lubricant prevent trouble from leakage at the gland. The spindle is supported by two ball bearings, totally enclosed, enabling the pump to be run at comparatively high speeds with a minimum of friction or wear and tear. Some of these small pumps have raised 85% nitric acid to a height of 60 ft. continually at temperatures up to 52° C. In one case five pumps pumped 22,000 tons of nitric acid without expenditure for maintenance.

THE AVAMORE "SQUEEGEE" PUMP.

BY R. A. PELMORE.

This pump, invented by Mr. N. G. Beckwith, comprises a rotor consisting of a disc loosely mounted on an eccentric on the shaft rolling round the inside of the pump casing. No sliding takes place between casing and rotor, but rolling motion is imparted to the rotor, which turns round the eccentric, the latter acting as a bearing. At the top of the casing a metal piece, usually with some spring tension behind, works up and down in a slot, keeping contact at all times with the rim of

the disc. Inlet and outlet ports are immediately to right and to left of this metal piece or valve. "Squeegee" action drives the liquid round in front of the rotor; the liquid, being sealed from the suction side by the valve piece, is driven through the delivery port, while at the same time liquid follows behind the rotor through the suction port.

The pump consists of a casing, end covers, a shaft and two discs with two valve pieces. The discs and valves are duplicated for perfect balance, even flow, and silent running.

The casing and rotor do not have sliding wear against each other. The sliding surfaces are the main bearing bushes for the shaft and the bore of the rotor disc on the eccentric. The discs rotate round their own centres at a speed proportional to the difference in diameter of casing and rotor, so that for a pump speed of, say, 1000 r.p.m. the rim of the disk only makes about 60 complete turns per minute past the valve piece, so making the wear there negligible.

The constructional simplicity and the restriction of principal wearing surfaces to bearings, as well as the absence of valves, without sacrificing the positive action or ability to run without priming, make a pump of extraordinary reliability.

By the addition of a simple attachment the delivery and suction connexions remain the same for either direction of rotation.

METHOD OF TRANSPORTING AND DISTRIBUTING LIQUIDS ABOUT A FACTORY.

BY H. W. CROW.

The device which is the subject of this note† provides a means of putting any given vessel in a factory into communication with any other by a kind of switch table, avoiding cocks, valves, and branch pipes, either directly or through the intermediary of a pump. Pipe lines are brought from a number of vessels to one point, terminating in such a way as to make a circle of short vertical pipes at the circumference of a table. The end of each short pipe is fitted with a cone union. Revolving round the centre of this circle are two radiating arms, one end of each capable of connection to any of the cone unions and the other ends connected to two loops, one above and one below, the further ends of which are connected with one another either through two bridge pieces and the suction and delivery of a pump or through one bridge piece direct. In this way any one of the short vertical pipes of the circumference of the table can be brought into connexion with any other and therefore any one of the vessels with any other of the group. By making

† See Eng. Pat. 130,946.

one or more of the short vertical pipes lead to corresponding short vertical pipes of other tables further groups of tanks can be brought into inter-communication.

It is preferable to arrange the tables at a higher level than the highest vessel. If this is not practicable small pet cocks should be fitted at the highest point in the pipes leading to the various vessels to prevent siphoning.

The table may be used in conjunction with its own pump or not. When the pump is not required one of the bridge pieces is swung on one side and the other connected straight across the two loop terminals. When an operation is completed it is possible, by slowing down the pump, to sweep the pipes all but free from liquid by allowing air to be sucked through.

PUMPING ACIDS AND OTHER CORROSIVE LIQUIDS, WITH PARTICULAR REFERENCE TO THE ARMoured CERATHERM CENTRIFUGAL PUMP.

BY W. HAYHURST.

Pumps for acid or corrosive liquids should be simple in construction and should, if possible, have no internal rubbing surfaces or bearings; there should be no contact between the corrosive liquid and material with which it can react; valves should be avoided if possible; any oil used should not come into contact with the corrosive liquid; the pressure developed by the pump should be easily variable from zero to about 50–60 lb. The type of pump which best fulfils these requirements is the centrifugal. Ceramic material is the most suitable for the construction of pumps for the chemical trade. The type chosen by the author for his pump was a form of Ceratherm, with considerably increased tensile strength and with sufficient heat-resisting capacity to enable the pump to be worked alternately on hot or cold liquids without liability to fracture.

In the Guthrie Ceratherm pump the casings are made exceedingly thick and strong. They are set into the iron armourings by means of acid-resisting cement. The inlet and outlet are so constructed that coupling up can be accomplished without any fear of damaging the pump. The acid or corrosive liquid is fed into the pump on the gland side. No trouble is experienced in packing this gland, which is continually under suction, a small quantity of wool, soaked in paraffin wax, if desired, being pressed home with the fingers. Heads of 200 or 300 ft. can be attained without any leak or trouble at the gland.

To fix the impellers on to the steel shaft the interior of the shaft of the impeller is filled with a cementing material of very high acid resistance, which receives a screw thread and the shaft is then screwed into the impeller, which is ground and balanced on its own shaft. The impellers are of very substantial construction. They have been tested up to fully 3000 revs. The Manx impeller, which is now being used largely, is almost self-balancing so far as thrust is concerned and gives very little thrust along the shaft.

In chemical works it is generally required to pump a small quantity (say 20–100 galls. per min.) to a head of anything up to 120 ft., whilst running the pump at low speeds. This means that the ratio of the diameter of the impeller to the width of its blade is necessarily high, and as this ratio is a factor which governs the theoretical efficiency of any centrifugal pump a corresponding reduction of efficiency would be expected.

In the neighbourhood of 40 ft. head efficiencies of 60% have been attained with these pumps, and with 120 ft. head about 40%.

MR. W. McD. MACKEY IN THE CHAIR.

THE DETERMINATION OF ALKALINITY IN TANNERY LIME LIQUORS.

BY W. R. ATKIN, M.Sc., AND W. E. PALMER, B.A.

(Abstract.)

The methods to be described have been devised with a view to overcoming certain defects in the methods at present employed in the determination of alkalinity in lime liquors. The factors which contribute to the alkalinity of lime liquors are: (a) calcium hydroxide, (b) sodium hydroxide, (c) sulphhydrates of calcium and sodium, (d) ammonia and amines, (e) sodium and calcium salts of weak acids or products of hydrolysis of hide proteins.

Total alkalinity is due to all the substances enumerated above and is determined by the method described by Bennett,¹ in which 25 c.c. of the filtered lime liquor is boiled with excess of N/10 sulphuric acid and the excess titrated with N/10 caustic soda, using methyl red as indicator. In all the lime liquors examined a precipitate was formed by this treatment with acid; these precipitates are due doubtless to dissolved keratinous matter and not to true hide substance, as was demonstrated by one of us recently.² This point was further tested by determining the total alkalinity of a solution of gelatin in lime water, in which case no precipitate was obtained on addition of acid. A similar result was noted with a solution of hide powder in lime water, although both solutions were very rich in nitrogen. By using N/10 reagents throughout, the titration for total alkalinity is a measure of $a+b+c+d+e$.

Caustic alkalinity is an important figure for the tanner, as it is a measure of the plumping power of the lime and has a pronounced influence on the subsequent leather produced. This caustic alkalinity is due to the hydroxides of calcium and sodium or to $a+b$.

Bennett³ has devised a method to determine this figure which is very ingenious, but in one important respect unsound. It depends on two titrations of the lime liquor after treatment with formaldehyde.

First titration.—10 c.c. of 40% formaldehyde solution diluted with 10 c.c. of distilled water is neutralised to phenolphthalein with N/10 caustic soda until a faint pink colour appears; 25 c.c. of the clear filtered lime liquor is added, and, after mixing, titrated with N/10 hydrochloric acid until the pink colour just disappears. During this titration the hydroxides of calcium and sodium are neutralised by the acid and not affected by the formaldehyde. Ammonia reacts with the formaldehyde to form neutral hexamethylenetetramine. Formaldehyde reacts with sulphhydrates and liberates an equivalent amount of hydroxide: $\text{NaSH} + \text{HCHO} + \text{H}_2\text{O} = \text{H.CH(OH)(SH)} + \text{NaOH}$, and thus all sulphhydrates are estimated. Formaldehyde also reacts with amino acids, producing methylene-amino acids, which react acid to phenolphthalein: $\text{NH}_2\text{R.COOH} + 11\text{HCHO} = \text{CH}_2\text{:N.R.COOH} + \text{H}_2\text{O}$. Consequently, after adding formaldehyde to a lime liquor methylene-amino acids are formed which neutralise a certain amount of the caustic alkalis, so that the caustic alkalinity and that due to sulphhydrates are reduced by this acidity produced by the amino acids. In other words, this titration

¹ Bennett. Coll. (London) 1915, 260.

² Thompson and Atkin. J. Soc. Leather Tr. Chem., 1920, 15.

³ Bennett. Coll. (London), 1915, 321.

affords a measure of $a+b+c$ —amino acids. The above explanation is that put forward by Bennett, and is quite sound. The calcium and sodium salts of the hydrolysis products are not affected in this titration.

Second titration.—25 c.c. of filtered lime liquor is neutralised to phenolphthalein with glacial acetic acid until the pink colour is discharged, and $N/10$ iodine added until an unabsorbed excess is observed. $N/10$ caustic soda is then added until a pink colour appears, and finally 10 c.c. of neutral formaldehyde. After mixing the solution is titrated with $N/10$ caustic soda until the pink colour reappears. Later this titration (originally described by Stiasny)⁴ was modified by using hydrochloric acid instead of acetic acid, as the end-point was found to be sharper.

Bennett states that this second titration is a measure of the acidity produced by the amino-acids, the caustic alkalis having been neutralised by the acid and the sulphhydrates decomposed by the iodine; consequently the number of c.c. of $N/10$ caustic soda found in the second titration added to the number of c.c. of $N/10$ hydrochloric acid for the first titration gives a measure of $a+b+c$.

Unfortunately he has ignored the fact that the free ammonia often present in considerable quantities has been neutralised with the formation of ammonium acetate (or ammonium chloride), which reacts with formaldehyde to liberate an amount of acid equivalent to the amount of ammonia present in the lime liquor and also to form hexamethylene-tetramine:

This omission is curious, as Bennett⁵ himself advocated the use of formaldehyde to replace the distillation with caustic soda in the Kjeldahl method of estimating nitrogen.

No mention has yet been made of the action of amines on formaldehyde. Primary amines, such as methylamine, seem to react with formaldehyde in a somewhat analogous way to amino acids as far as the NH_2 is concerned.

With their hydrochlorides hydrochloric acid is liberated, just as in the case of ammonium chloride. This point was tested experimentally with methylamine hydrochloride.

The hydrochlorides of secondary and tertiary amines apparently do not behave in the same way as those of the primary amines. However, Effront⁶ has tested for trimethylamine in many different putrefactions, but has not succeeded in detecting it, and states that only materials containing betaine or trimethylglycine give rise to trimethylamine.

The constitution of the amino-acids known to be components of hide proteins does not suggest the likely formation of di- or tri-methylamine by putrefaction. Accordingly only a relatively small error will be introduced by assuming that the whole of the ammonia and amines obtained by distillation reacts with formaldehyde, causing the liberation of an equivalent amount of hydrochloric acid. Thus the second formaldehyde or Stiasny titration measures the amino-acids plus ammonia and amines, or d +amino acids. The sum, therefore, of the two formaldehyde titrations is a measure of $a+b+c+d$, and by subtracting $e+d$, that is c.c. $N/10$ acid required for ammonia, amines, and hydrosulphides, $a+b$ is obtained, which is the caustic alkalinity of the lime liquor.

ESTIMATION OF ALCOHOL IN MIXTURES OF ALCOHOL, SULPHURIC ACID AND WATER.

BY G. S. BUTLER, B.A., F.I.C., AND H. B. DUNNICLIFF, M.A., B.Sc., A.I.C.

In the course of an investigation on the possibility of recovering sulphuric acid from nitre cake by spirits of wine, a large number of solutions of sulphuric acid in alcohol were obtained in which it was necessary to have a reliable method of estimating the constituents. It was hoped that the method due to F. G. Benedict and R. S. Norris (J. Amer. Chem. Soc., 1898, 20, 293) would be suitable, but it was not found possible to get concordant results by this or by several other methods.

In all alcoholic sulphuric acids partial esterification is observed, even in the presence of considerable quantities of water. The method to be described involves the estimation of the alcohol both as ethyl hydrogen sulphate and as free alcohol. It has been found that if the free sulphuric acid is estimated by titration by the method to be described, the results show good agreement with those obtained by precipitation of the free sulphuric acid as barium sulphate and weighing the precipitate. This shows that, during titration, no appreciable hydrolysis takes place.

The combined alcohol is estimated by determining the amount of acid which has undergone esterification. A weighed quantity of the alcoholic sulphuric acid is titrated against standard alkali. This "direct" titration gives b (see Table I.) the percentage of acid present in terms of sulphuric acid, i.e., it gives the free sulphuric acid and the acidity due to ethyl hydrogen sulphate (in terms of sulphuric acid).

The "total" acidity is found by evaporating a weighed quantity of the alcoholic sulphuric acid to a pasty consistence with excess of standard caustic soda or potash, heating in an air oven at 120°C . for half an hour, and then, after extraction with distilled water, titrating the excess alkali with standard acid. From this is calculated the percentage acidity of the alcoholic sulphuric acid before any esterification took place. The value is expressed as percentage of sulphuric acid, a . Thus, the percentage of acid esterified = $2(a-b)/a \times 100$.

The weight of esterified alcohol in 100 grams of the alcoholic sulphuric acid is $2(a-b)/a \times 100 \times 46 \div 98$ grams.

* Mean of five determinations.

The free alcohol may be determined by weighing out 25 grms. of the alcoholic sulphuric acid, making

faintly alkaline with sodium carbonate, and distilling until about 95 c.c. of distillate has been collected. This treatment does not hydrolyse the ester, and the distillate contains all the uncombined alcohol present. The distillate is made up to 100 c.c., and its density at 60° F. determined. The percentage of alcohol present is obtained from a table, and this quantity multiplied by four gives the weight of uncombined alcohol present in 100 grms. of the alcoholic sulphuric acid.

Table I. gives the results of determinations made for the same solution and showing the slow but continuous increase in esterification up to a maximum with lapse of time. Table II. gives a series of results obtained for alcoholic sulphuric acids of various concentrations. The solutions were made up in each case by mixing weighed quantities of alcohol and sulphuric acid, both of known strength.

THE ACTION OF CONCENTRATED SULPHURIC ACID ON IRON.

PART III.*

BY CHARLES E. FAWSITT.

There exists some uncertainty as to the safety of transporting concentrated acid in iron or steel drums, and much more investigation is required on the action of sulphuric acid on iron on account of the importance of the matter in chemical industry.

Some of the factors which influence the action are:—(a) the kind of iron used—this depends on the chemical composition and also on the structure of the metal; (b) the nature of the surface of the iron, i.e., whether rough or smooth, or covered by any film of solid, liquid, or gaseous substance (Fawsitt, this J., 1906, 1134); (c) the concentration of the acid; (d) the temperature; (e) the presence of impurities, or additions of foreign substances to acid or iron; (f) mechanical influences, such as shaking.

The factors under headings (a) and (d) were to some extent discussed in the first paper (this J., 1914, 234). Some work under heading (c) has been done by Knietsch (this J., 1902, 343), and a record of further work has appeared in a recent paper (Fawsitt and Pain, Proc. Roy. Soc. N.S.W., 1918, 52, 396; see this J., 1920, 193 A).

The manner in which the addition of water increases the rate of action on iron depends apparently on the kind of iron used. Using steel wire containing C 0.51, P 0.016, Si 0.083, S 0.058, Mn 0.48%, the velocity of action, found by Fawsitt and Pain, is as indicated in Table I. When the acid and steel were shaken together the rate of action was measured by weighing the steel before

and after action, but these results are also calculated to show the average volume of gas evolved.

TABLE I.

Weight of steel used, 5 grms.; surface, 36 sq. cm.; temperature, 30° C.; time, 28 days.

Concentration of sulphuric acid (% of H ₂ SO ₄).	Average vol. (for 28 days) of gas evolved in c.c. per hour per sq. cent. of steel surface.	Steel and acid shaken together.	
		Loss of weight of steel in 28 days (grms.).	Calc. average vol. of gas evolved during 28 days (c.c. per hr. per sq. cent.).
97.4	—	0.090	0.17
91.0	0.27	0.861	1.46
90.0	0.31	1.222	2.07
89.3	0.66	0.140	0.21
87.9	0.28	0.523	0.89
85.0	0.30	0.526	0.89
80.0	2.5	2.915	4.91

With the particular class of steel used here, the velocity increases as the acid is diluted from 97% to 90.9% H₂SO₄; it then appears to drop rather suddenly at the next concentration (89.3%). After the concentration has dropped to 85% the velocity increases very decidedly. It would be of interest to examine the effect of concentration on velocity rather exactly between 91% and 88% H₂SO₄.

Further experiments under heading (f), carried out since the publication of the first paper, all show that shaking has an important effect in increasing the velocity of action.

Experiments would indicate that with commercial acid and any particular kind of iron, a certain maximum rate of action is sometimes capable of being realised. When a drum of acid is being transported it is safer to assume that the maximum rate of action may take place, and the maximum pressure of gas, after a given time, could be calculated from the dimensions of the drum, the volume of the air space above the acid, the temperature, and laboratory experiments with the same iron and the same acid. The maximum rate of action is, however, not always attained.

It has sometimes been found that although there may be a pressure of gas in one drum of acid, there is little or no pressure in other drums of the same kind, filled with the same acid, and exposed to exactly the same conditions, as far as can be judged. So long as calculations are based on the maximum rate of action, no harm can result from a smaller rate being actually observed, but it is disconcerting to find this great difference in behaviour between a number of drums.

Among other considerations, it is possible that the reason the iron is not always acted on at the maximum rate is that the iron may sometimes go into a passive state, and so not be acted on by the sulphuric acid. There may be more than one kind of passive iron, but the readiest means of producing a passive iron is to leave iron for a few moments in nitric acid of sp. gr. 1.4. It may easily be shown by E.M.F. measurements that iron, lying in concentrated sulphuric acid, and apparently not being acted upon by the acid, is not usually in a passive state. On the other hand, passivity is recorded (Heathcote, this J., 1907, 899—917) as being produced on iron sometimes simply by exposing iron to air. The author has never come across a case where a piece of iron or steel, that had been lying in the air (and otherwise untreated), showed passivity towards concentrated sulphuric acid; but if the iron of a drum could become wholly (or perhaps even partially) converted into passive iron, by lying in the air or otherwise, it is quite possible that such iron might retain its passivity after the sulphuric acid had been put in.

* For Parts I. and II. see Fawsitt and Powell, this J., 1911, 234.

Many experiments have been carried out by the author, where steel that had been wholly treated by nitric acid of sp. gr. 1.4 was passive towards concentrated sulphuric acid. The passivity is detectable both by E.M.F. measurements and by the observation that little or no solution of the steel takes place. Every case tried did not succeed.

A curious effect has been noticed by the author. If a piece of steel is dipped for only part (say half) of its length into nitric acid of sp. gr. 1.4 and then dipped wholly into concentrated sulphuric acid, in many cases no action on the steel is apparent for several days at least,* either on the lower (passivified) part or the upper part. This might be thought to be due to a "wave of passivification" passing over the whole iron (just as the activating proceeds by propagation from one part of the iron to the other; see Heathcote, this J., 1907, 899—917). This is not the real explanation, however, as the upper portion originally not acted on by the nitric acid becomes immediately coated with a white film of ferrous sulphate, while the lower portion, which has been acted upon, is unaffected. The upper part, although originally of a greater solution pressure than the lower, probably becomes polarised and will no longer dissolve.

Experiments were also carried out with the addition of certain substances to the acid in the hope that the action might be found to be decreased by certain additions, and the results are shown in Table II. Unfortunately no experiment has yet shown that any addition to the acid is decidedly helpful in preventing action. In these experiments the tubes containing 40 c.c. of acid and 3.5 grms. of steel were not shaken. The steel was weighed before and after each experiment. On lifting the tube from the thermostat, the acid was poured off as completely as possible and the steel washed twice with alcohol, then with water, and finally with alcohol; it was then dried and weighed. The surface of the steel exposed to the acid in each case was approximately 25 sq. cm. Before using fresh steel wire in these experiments it was first treated with sodium hydroxide solution, and then with water. In many cases, however, the steel was used in a second experiment; it was then used exactly as it came from the first experiment (after washing with alcohol and drying).

The same steel wire was used in all the experiments as already described for Table I. (*loc. cit.*)

It will be noticed that although preliminary treatment with concentrated nitric acid may to a certain extent preserve the steel from being afterwards attacked by the concentrated sulphuric acid, putting nitric acid or nitrates into the sulphuric acid increases the rate of action very much.

While dipping iron into concentrated nitric acid either wholly or partially and then placing in concentrated sulphuric acid may bring about a state of passivification which persists for some considerable time, this is not by any means always the case.

When the passivification is either not effected, or only effective for a few hours or days, the small quantity of nitric acid in the solution enormously increases the rate of action of the acid on the iron. This is shown by the results of several experiments at 30° C. for 44 days with 96.3% H_2SO_4 , using 3.5 grms. of steel in each case. In the first two experiments, in which the steel received no preliminary treatment, the loss of weight was 0.132 gm. and 0.238 gm. respectively. In another experiment one-third of the steel was covered with concentrated nitric acid; this was poured off and concentrated sulphuric acid added to cover (the same) one-third of the steel and poured off. Then 40 c.c. of concentrated sulphuric acid was added. In this case the loss of weight was 0.047 gm. In a further experiment with the same treatment as the last, but with only one-quarter of the steel treated with

nitric acid, the loss of weight was 1.37 grms., whilst when the whole steel was treated with concentrated nitric acid the loss was 1.52 grms. It appears, then, that although preliminary treatment of the steel with concentrated nitric acid cannot yet be recommended as a means to be generally used in preventing subsequent action of the sulphuric acid, this is not an unpromising line for further experiment.

TABLE II.

No. of experiment.	Temperature.	Concentration of sulphuric acid (by analysis).	Additions to sulphuric acid.	Time (in days) of immersion in acid.	Loss of weight of steel, grms.
1	28° C.	91.5	None.	18	0.48
2	28° C.	91.5	0.04 gm. potassium persulphate.	18	0.44
3	28° C.	91.5	0.08 gm. sodium sulphate.	18	0.43
4	28° C.	91.5	0.06 gm. sodium hydrosulphite.	18	0.44
5	28° C.	91.5	0.09 gm. potassium bisulphate.	18	0.22
6	30° C.	91.5	None.	4	0.068
7	30° C.	91.5	0.019 gm. potassium nitrate.	4	0.124
8	30° C.	91.5	None.	13	0.19
9	30° C.	91.5	0.016 gm. arsenious oxide.	13	0.103
10	30° C.	96.3	None.	13	0.064
11	30° C.	96.3	0.06 gm. arsenious oxide.	13	0.078
12	30° C.	96.3	0.052 gm. lead nitrate.	13	0.393
13	30° C.	96.3	0.08 gm. HNO_3 (sp. gr. 1.4).	13	0.58
14†	30° C.	96.3	None.	13	0.015
15†	30° C.	96.3	None.	13	0.0257

† In experiments 1—13 the iron received no special preliminary treatment. In experiment 14 the steel was wholly covered with nitric acid of sp. gr. 1.4, this was poured off, sulphuric acid added and poured off; a little more sulphuric acid added and poured off; then the usual 40 c.c. conc. sulphuric acid added. In experiment 15 one half of the steel was covered with nitric acid of sp. gr. 1.4 which was then poured off and 40 c.c. conc. sulphuric acid added; strong action took place at first, but after 2 days apparently no action was going on.

It was also thought advisable to try the effect of putting certain metals in contact with iron while immersed in concentrated sulphuric acid. A metal might be expected to dissolve more readily in an acid if it were in contact with a metal electro-negative to it. This effect, however, is sometimes obscured by polarisation effects when both the metals are completely covered by the acid. Variable and no encouraging results were obtained with the use of either aluminium or platinum in contact with iron (Table III.).

It was not thought worth while to try metals like magnesium or zinc, because it was considered that as concentrated sulphuric acid acts on these metals, gas would in any case be evolved, even if they protected the iron.

TABLE III.

Temperature.	Concentration of acid, H_2SO_4 , %.	Metal touching steel.	Time of immersion in acid, Days.	Loss of weight of steel, grms.
30° C.	91.5	None.	4	0.068
30° C.	91.5	Mercury.	4	0.061
25° C.	91.5	None.	11	0.134
25° C.	91.5	Platinum.	11	0.123
25° C.	91.5	Aluminium.	11	0.071
25° C.	96.3	None.	27	0.048
25° C.	96.3	Platinum.	27	0.048
25° C.	96.3	Aluminium.	27	0.055

A possible line of investigation seems, therefore, to be one where the iron is previously made passive under such conditions that no nitric acid gets into the sulphuric acid.

MR. L. P. WILSON IN THE CHAIR.

THE ESTIMATION OF CARBON DIOXIDE AND FERMENTABLE SUGARS.

BY ARTHUR SLATOR, D.S.C.

The apparatus described in this communication was devised originally to estimate the total amount of carbon dioxide formed when sugars are fermented by yeast. It was subsequently found to be of general use, and can be employed in most cases where it is necessary to estimate this gas. The apparatus consists of a distillation flask, A, con-

nected to a condenser, C, in the manner shown in the diagram. The large trap, B, prevents spray and froth being carried over during the distillation of carbon dioxide from A to the "assay" flask, E, which contains standard baryta water. G is a test tube to which has been sealed a piece of glass tubing. This tube can be connected to the side piece, D, by means of pressure tubing, H. The whole apparatus can be exhausted through the stopcock, F. The estimation of carbon dioxide in sodium carbonate is carried out in the following manner: 25 c.c. of N/10 sodium carbonate is placed in A, and G is filled with dilute sulphuric acid. Into E is introduced 30 c.c. of N/10 baryta water. The apparatus is exhausted, a screw clip being

placed at H to prevent the acid in G passing into A. F is then closed and the clip removed. The acid in G is warmed and boils into A. Both A and G are then well boiled and E shaken to absorb the gas. When the distillation is complete, air free from carbon dioxide is allowed to enter the apparatus through F. The excess of baryta in the turbid solution in E is then titrated with standard hydrochloric acid, using phenolphthalein as indicator. Previous tests made by titrating baryta water containing a suspension of barium carbonate showed that rather more standard acid is required to change the bright pink colour to a faint pink than is necessary when no carbonate is present. The correction amounted to 0.15 c.c. of N/10 solution. In these estimations this correction is added to the apparent amount of alkali neutralised by the carbon dioxide. 25 c.c. of N/10 sodium carbonate was found to yield carbon dioxide sufficient to neutralise 25.05, 25.15, 24.7, 25.05, 25.05 c.c. of N/10 baryta water (theory 25.0 c.c.).

A drinking water was analysed for total carbonate. Dilute sulphuric acid was placed in A. G was replaced by a funnel through which the water to be analysed was run into the exhausted apparatus. 250 c.c. was found to yield CO_2 equivalent to 14.25, 14.25 c.c. of N/10 alkali. The same water showed 15.5° temporary hardness (parts CaCO_3 in 100,000) by direct titration, using methyl orange as indicator. The figures show slight excess of lime over the carbon dioxide calculated as bicarbonate. The carbon dioxide in calcium carbonate can be estimated by distillation with phosphoric acid. A specimen which was practically pure (0.2 g. neutralised 40.1, 39.9 c.c. of N/10 HCl) gave the following result: 0.2 g. CaCO_3 gave CO_2 which neutralised 40.0, 39.95 c.c. of N/10 baryta (theory 40.0 c.c.).

Free carbon dioxide in liquids can be estimated by filling G with the liquid and subsequently distilling off the carbon dioxide. Carbon dioxide formed in certain oxidation reactions can be collected and estimated by means of this apparatus. 0.0953 g. of potassium tetraoxalate $\text{KH}_2(\text{C}_2\text{O}_4)_2 \cdot 2\text{H}_2\text{O}$ was oxidised in the apparatus with slight excess of acidified permanganate solution and found to yield CO_2 to neutralise 29.9, 30.15 c.c. of N/10 baryta water (theory 30.0 c.c.).

These examples show the general use to which the apparatus can be put for estimating carbon dioxide. Special precautions have to be observed if volatile acids other than carbon dioxide are present, and if insoluble salts are present care has to be taken that all the carbonate is acted upon by the acid, but in most cases the method is very satisfactory.

The estimation of sugars by alcoholic fermentation offers possibilities which are of some interest. If the fermentation reaction can be put on a quantitative basis, it should be possible to estimate sugars and mixtures of certain sugars and other carbohydrates without utilising the optical activity or the reducing properties of the sugar. Pure cultures of yeasts containing definite enzymes have been used successfully by Davis and Daish (J. Agri. Sci., 1913, 5, 437) to estimate sugars. The fall in reducing power or the change in optical activity after complete fermentation measures the amount of sugar present. The idea here is to extend the use of these pure cultures and employ the fermentation reaction itself to estimate the sugar. The matter was tested in the following way.

Into tubes (K) were introduced measured quantities of solutions of pure sugars, 2 c.c. of yeast water (sp. gr. 1.017) and water to make up the volume to about 12 c.c. The tubes were plugged with cotton wool and then sterilised. Each tube was seeded with a pure culture of yeast, the tube heated at L and the glass pulled out to a fine capillary. The tube was then exhausted and sealed at L. Fermentation was allowed to proceed at 25° C., the tubes

being shaken each day. The carbon dioxide produced was estimated in the following way. A file mark was made at M on the tube, which was then connected to the apparatus. After exhausting the flask and boiling the water in A, F was shut off and the end of the tube broken at M in the pressure tubing. The tube and flask were then both warmed and all the carbon dioxide collected in E.

The following results were obtained by fermenting about 0.1 g. of sugar with a pure culture of brewery yeast and with a culture of *S. apiculatus*, which ferments dextrose and levulose but not maltose or sucrose.

The yeast water gave $\text{CO}_2 = 0.15$ c.c. N/10 baryta water, and the correction was made on the final titration.

In Table I A=c.c. N/10 baryta water neutralised by CO_2 from 0.0988 g. of dextrose (theory 21.9 c.c.) by fermentation with a pure culture of brewery yeast. B=ditto from 0.09895 g. of sucrose (theory 23.2 c.c.). C=c.c. from 0.0960 g. of dextrose fermented by the *apiculatus* yeast (theory 21.35 c.c.).

In A and B carbon dioxide equivalent to the sugar originally present has been evolved, in C lower results have been obtained, but even here the degree of accuracy is as great as one would expect from a biological method of this kind. In the first two cases the claim is not made that the sugar is completely fermented according to the equation $\text{C}_6\text{H}_{12}\text{O}_6 = 2\text{CO}_2 + 2\text{C}_2\text{H}_5\text{OH}$. Probably about 95% of the carbon dioxide is produced according to this equation, another 2% comes from the auto-fermentation of the yeast, and the rest from the auto-digestion of the yeast. In the last case carbon dioxide may be produced from substances other than sugar.

A test was made to determine if the method could be applied to estimate some of the constituents of ordinary brewery wort. A wort of gravity 1.040 contains approximately 10 g. of dissolved substance in 100 c.c. Of this 10 g. about 1 g. is dextrose and levulose, $\frac{1}{4}$ g. is sucrose, $\frac{5}{16}$ g. maltose and fermentable maltodextrins, 2 g. dextrin and unfermentable maltodextrins, and $\frac{1}{2}$ g. proteins, mineral salts, etc. Fermentation with the *apiculatus* yeast should estimate dextrose and levulose only. 1.5 c.c. of wort (gravity 1.055) was introduced into the tube, diluted and fermented in the manner described. It gave CO_2 neutralising 3.7, 3.8, 3.6 c.c. of N/10 baryta water. Further experiments were made in which small quantities of dextrose (0.05—0.10 g.) were added to the wort before fermentation. The increase in the amount of the carbon dioxide produced corresponded to 92.6, 92.6, 92.6, 93.5, 91.9, 92.6 (average 92.6) % of the theoretical amount. The results are consistent, but only 92.6% instead of 97% of the theoretical yield of carbon dioxide is obtained. Using this factor the amount of dextrose and levulose in the original wort = $3.7 \times 100 \times 100 \div (222 \times 92.6 \times 1.5) = 1.20$ g. per 100 c.c. The total amount of fermentable carbohydrates in wort can be determined in the following way: the wort is fermented with yeast, filtered, and the alcohol distilled off from a measured volume. The residue is made up again to this volume and the process repeated. From the gravity of the final residue the total amount fermented can be

calculated. A wort of gravity 1.0393 produced a residue 1.0136. This corresponds to a spirit indication 5.85 or 3.21 g. of alcohol per 100 c.c. This is equivalent to 3.07 g. CO_2 . In a fermentation of this kind about 95% of the theoretical yield of alcohol is obtained. The theoretical yield of carbon dioxide in the above case would be 3.23 g. 2.25 c.c. of wort diluted and fermented gave CO_2 neutralising 32.1, 32.2, 32.4 c.c. of N/10 baryta water (average 32.2). 100 c.c. wort therefore gives $32.2 \times 100 \times 2.2 \text{ g.} \div (2.25 \times 1000) \text{ g.} \text{CO}_2 = 3.15 \text{ g.}$ Though the calculation is only approximate, it is evident that the total amount of fermentable carbohydrates can be obtained in this manner with a fair degree of accuracy.

The conclusion drawn from a number of experiments carried out in this manner is that small quantities of sugars can be estimated by this fermentation method, but that it is advisable to carry out control experiments with pure sugars before using the method for any special purpose. It has been shown that small quantities of sugars can be fermented away by large amounts of yeast within a few hours (J., 1908, 653). It is possible to carry out such fermentations in sealed tubes and estimate the sugars by titrating the carbon dioxide produced. A blank experiment has to be carried out to correct for the auto-fermentation of the yeast. The method, however, is inconvenient, and details of the estimations are not included in this communication.

The presence of certain enzymes in yeasts serves to characterise and identify different races of yeast. Care has to be taken in detecting such enzymes, and some of the results given in the literature are certainly incorrect. The following method is recommended for carrying out such tests. For the detection of invertase tubes containing yeast water, sucrose (0.2 g.) and dextrose (0.02 g.) are inoculated with a pure culture of the yeast. The tubes are exhausted and sealed up. After about a week the carbon dioxide is distilled off and estimated. If no invertase is present in the yeast, carbon dioxide to neutralise about 4 c.c. of alkali is obtained; if present, up to 40 c.c.—50 c.c. is neutralised. The presence of dextrose is an advantage for growth and a certain amount of fermentation is insured. Maltase can be detected by using maltose in place of sucrose. The presence of or absence of galactozymase can be shown by using galactose.

The following results were obtained:

TABLE II.

Yeast.	Enzyme.	Alkali neutralised.	Presence or absence of enzyme.
		cc.	
<i>Apiculatus</i>	Invertase	3	—
	Maltase	3.7	—
<i>Cerevisia</i>	Galactozymase	31	+
Wild yeast A	..	34	+
.. B	..	2.5	—
.. C	..	32	+

Many methods of estimating carbon dioxide have been described in the literature on the subject, and no great originality can be claimed for this apparatus. It is, however, of general use, and can be applied especially to estimate carbon dioxide from fermentation reactions.

Prof. G. T. MORGAN said that in 1904 he had suggested the use of phosphoric acid in the estimation of carbon dioxide in naturally occurring carbonates. The non-volatility of the acid effected a simplification in the apparatus, since pumice impregnated with dry copper sulphate was not required as was the case when hydrochloric acid was used to decompose the carbonate. A mixture of

phosphoric and chromic acids enabled one to estimate in a similar way the carbon present in organic compounds, even when these were very resistant to oxidation, and the process could be used for carbon in steel (Chem. Soc. Trans., 1904, 85, 1004).

Dr. E. W. SMITH said that in testing for carbon dioxide in the atmosphere he had found that where great accuracy was required it was necessary to use bottles coated with paraffin wax. Did the author consider that the precautions of the Pettenkofer method were worthy of consideration for his purpose?

Dr. SLATOR said, in reply, that he had not tested other oxidation reactions, but they could doubtless be carried out in the apparatus, and the resultant carbon dioxide estimated. Care must be taken not to employ reagents which produce free oxygen. No difficulties such as occurred in estimating carbon dioxide by Pettenkofer's method were met with in these experiments.

MR. W. MCD. MACKEY IN THE CHAIR.

SOME OBSERVATIONS ON THE "SPRINGING" OF "CARBOLATE" AND THE RECOVERY OF PHENOL FROM THE RESULTING AQUEOUS LIQUOR.

BY H. M. DAWSON.

In the "springing" of "carbolate" by the addition of sulphuric acid a considerable proportion of the phenol remains in the resulting aqueous solution of sodium sulphate which is run off to the drain. The proportion of carbofic acid which is thereby lost depends largely on the conditions under which the "carbolate" is "sprung." The percentage loss is mainly determined by the volume of the aqueous liquor, by the concentration of the sodium sulphate in this solution, and by the temperature at which the separation of the phenol layer takes place. At a given temperature the percentage loss of phenol increases with the volume of the aqueous solution, but more rapidly than this, in that the resulting diminution of the concentration of the sodium sulphate lowers the "salting out" effect of the electrolyte on the phenol. When the volume of the aqueous solution and the concentration of the sodium sulphate are fixed, the percentage loss of phenol increases with rise of temperature.

The influence of the sodium sulphate concentration (C_2) on the phenol content of the aqueous liquor (C_1) is shown by the following numbers obtained from experiments made at 25° C. The concentrations are expressed in grams per litre, and in the third column are given the phenol concentrations calculated from the empirical equation—

$$\log C_1 = 1.92 - 0.0036 C_2 \dots (1).$$

Relation between phenol and sodium sulphate concentrations.

Sodium sulphate.	Phenol concentration.	
	Observed	Calculated
0	85.5	83.2
50	53.0	55.0
100	36.2	36.3
150	24.0	24.0
200	16.0	15.8
250	11.5	10.5

From the above relation between the phenol and sulphate concentrations it is possible to calculate

the percentage loss of phenol at 25° under any specified conditions of the springing process. Assuming that the quantities of phenol, sodium hydroxide, and sulphuric acid are equivalent, so that the "springing" is quantitatively represented by the equation

the percentage loss may be derived as follows:—Let W be the total quantity of phenol in the carbolate, C_1 the concentration of phenol, and C_2 the concentration of sodium sulphate in the resulting aqueous solution in grms. per litre. Then $W/142/188$ is the quantity of sodium sulphate produced, $142W/188C_2$ is the volume of the aqueous solution in litres, $142WC_1/188C_2$ is the quantity of phenol in the aqueous solution, and p , the percentage loss of phenol, is given by

$$p = 142WC_1/188C_2 \times 100/W = 75.5 C_1/C_2 \dots (2).$$

Since C_1 is a function of C_2 , the percentage loss of phenol can be expressed in terms of the sodium sulphate concentration. Substituting for C_1 the value given by equation (1), we obtain for p under the specified conditions:—

$$p = 75.5 (10^{1.92 - 0.0036C_2})/C_2 \dots \dots (3)$$

For the range of sodium sulphate concentrations which may be said to be of practical significance the percentage losses of phenol are shown in the following table, the numbers under p being derived from equation (2), and those under p_1 from equation (3).

Sodium sulphate concentration.	p	p_1
100 grms. per litre	27.3%	27.4%
125 " "	18.1%	17.8%
150 " "	12.1%	12.1%
175 " "	8.5%	8.4%
200 " "	6.0%	6.0%

In practice the conditions of the "springing" process vary considerably, and there is a correspondingly wide variation in the percentage loss of phenol. Assuming that the "carbolate" is obtained by the use of a 10% solution of caustic soda, that the dissolved phenol is equivalent to the sodium hydroxide in solution, and that the solution of the phenate is sprung by the addition of 65% H_2SO_4 (110° Tw.), the loss of phenol is about 10%. A laboratory experiment carried out under these conditions at 25° C. gave a loss of 9.5%.

It seems probable that the loss under actual working conditions may sometimes be appreciably greater than 10%, for the solution obtained under the above conditions contains sodium sulphate in such quantity that it deposits Glauber's salt at temperatures not much below 25° C., and this deposition is, of course, to be avoided in practice.

The loss of this phenol was at one period during the war a matter of considerable importance, and, at the suggestion of the Explosives Supply Department of the Ministry of Munitions, experiments were made with a view to the recovery of the phenol from the waste sodium sulphate liquors.

Preliminary observations, in which methods depending on adsorption of the phenol by solid substances and on extraction by liquid solvents were tried, led to the conclusion that the removal of the phenol from the aqueous liquors was more likely to be achieved by the use of liquid extraction media. In such extraction processes the efficiency is determined by the distribution ratio, i.e., by the ratio of the concentrations of the phenol in the extracting liquid and in the aqueous solution when the two media are in equilibrium. Apart from the magnitude of this ratio the extracting liquid should be readily available, should be only slightly miscible with water, and should be such that it can be easily separated from the phenol, which, by its use, has been extracted from the waste liquors.

The literature affords but little information as to the distribution of phenol between organic solvents and water, although the behaviour towards benzene and water has been examined in some detail. For dilute solutions, not exceeding, in the case of the aqueous layer, a concentration of about one gram per litre, Philip and Bramley (J. Chem. Soc., 1915, 107, 377) have shown that the ratio (r) of the concentration in the benzene to that in the water layer is independent of the absolute concentration. These experiments give $r=2.18$ at 25° . At higher concentrations experiments of Rothmund and Wilsmore (Z. physikal. Chem., 1902, 40, 611) show that r increases at 25° C. from 2.28 to 12.24 when the concentration of the phenol in the water layer is increased from 2.5 to 50 g. per litre. These results indicate that the distribution is very largely dependent on the concentration, unless the quantity of phenol in the aqueous layer is small in comparison with that present in a solution saturated with phenol at the same temperature.

In the experiments described in this paper no attempt has been made to investigate in any detailed manner the distribution of phenol between water and the various extraction media. The requisite information has been obtained by a direct determination of the quantity of phenol extracted by various solvents from an aqueous solution containing 10 g. of phenol and 200 g. of sodium sulphate per litre. In the experiments 50 g. of the extraction solvent was shaken at 25° C. with a litre of this solution, and after the non-aqueous layer had completely separated, it was dried, weighed, and the proportion of phenol in it estimated by appropriate methods.

The liquids used as extraction solvents are indicated in the first column of the following table. The "petrol" was a hydrocarbon fraction boiling at 95° – 100° C.; the solvent naphtha boiled between 145° – 155° C., and the "meta-cresol" was a mixture of *m*-cresol and *p*-cresol containing about 75% of *m*-cresol. The second column gives the quantity of phenol extracted from the aqueous solution by the various solvents, and the sixth gives the percentage of phenol recovered. In the third and fourth columns are shown the concentrations of the phenol, in grams per litre, in the non-aqueous and aqueous solutions respectively, and in the fifth is given the distribution ratio which is derived from these numbers:—

Extraction of phenol from aqueous solutions.

(1)	(2)	(3)	(4)	(5)	(6)
"Petrol" ..	0.47g ..	6.85 ..	9.53 ..	0.72 ..	4.7%
Solvent naphtha ..	3.99g ..	64.6 ..	6.01 ..	10.7 ..	40%
Benzene ..	4.13g ..	67.2 ..	5.87 ..	11.4 ..	41%
Nitrobenzene ..	6.49g ..	138.0 ..	3.51 ..	39.3 ..	65%
Ortho-cresol ..	7.49g ..	134 ..	2.51 ..	53.5 ..	75%
"Meta-cresol" ..	7.47g ..	130.5 ..	2.53 ..	51.5 ..	75%

In reference to the foregoing table it may be pointed out that nitrobenzene was included amongst the extraction solvents submitted to investigation because a knowledge of the influence of the nitro-group on the miscibility of phenol with the corresponding aromatic hydrocarbon was required in another connexion, and not because it could be regarded as a suitable extraction solvent even if the distribution ratio were extremely favourable.

The results obtained with the various solvents show that the cresols are the most effective in removing phenol from its aqueous solutions. The aromatic hydrocarbons are much less efficient, and the paraffin hydrocarbons, as represented by "petrol," are obviously quite unsuitable for use in the recovery of phenol. The relatively high recovery values obtained for the cresols are quite in keeping with the fact that miscibility is generally favoured by similarity in chemical nature. The closeness of the results obtained with *o*-cresol and

"meta-cresol" indicates that the solvent power of the cresols for phenol is not sensibly affected by the relative positions of the CH_3 and OH groups in the molecule.

From the experimental results obtained it may be inferred that a "cresylic acid" of relatively high boiling point could be used advantageously for the removal of phenol from its aqueous solutions. The aqueous liquors need only be agitated with about 5% by weight (or volume) of the "cresylic acid," and if the stripping is carried on in such a way that partially stripped liquors are brought into contact with fresh "cresylic" whilst the original aqueous liquors are agitated with "cresylic" which has already been used, a recovery of 90–95% of the phenol can readily be obtained. From the resulting mixtures of phenol and cresols the phenol can be removed in the usual manner.

DISCUSSION.

Mr. C. P. FINN pointed out that in tar-works practice the separation of phenol from the aqueous liquor tended to occur automatically in that the "carbulates" contained considerable proportions of cresols. He asked whether the author could suggest a suitable treatment for water which separates from cresosote and contains traces of phenolic substances.

Dr. DAWSON agreed that in the "springing" of "cresolates" containing phenolate the phenol would tend to be removed from the aqueous layer in virtue of the relatively high solubility of phenol in the cresols. The "carbulates" which the author had more particularly in mind were, however, those obtained in the production of synthetic phenol. The experiments which had been made with various solid adsorbents had not brought to light any material suitable for continued use in the removal of traces of phenolic substances from aqueous solutions.

Communication.

DETECTION OF MINUTE QUANTITIES OF PETROLEUM SPIRIT IN VEGETABLE OILS.

BY MASAHIRO AIDA.

A number of methods for the detection of petroleum spirit in vegetable oils have been proposed. A careful study of these has shown that they are not satisfactory, but it has been found that Nastjukoff's formolite reaction may be applied successfully for the purpose as follows:—

The oil (50–100 g.) is saponified by means of potassium hydroxide solution. Distilled water and pure calcium chloride solution are added, the liquid distilled by means of steam, and the distillate treated with 40% formaldehyde solution and a few drops of concentrated sulphuric acid. A reddish-brown film coloration on the surface of the liquid, gradually changing to deep yellow, indicates presence of petroleum spirit. If a few drops of the distillate are added to water, a brilliant interference ring of optical waves is produced on the surface of the water; this ring becomes almost invisible after standing for some time and disappears completely on heating. With soya bean oil the ring does not change, even on heating. The above process is capable of detecting traces of petroleum spirit in vegetable oils, and may be made the basis of a quantitative method, the formolite precipitate being weighed after drying at 110° – 115° C.

Thursday, March 11, 1920.

MR. L. P. WILSON IN THE CHAIR.

CATALYSIS APPLIED TO THE OXIDATION OF OILS.

BY R. S. MORRELL, M.A., PH.D., F.I.C.

In the linoleum, paint, and varnish industries the problems of the oxidation of oils are of the highest importance. The acceleration of the setting and drying times of oils introduces the study of the action of siccatives.

The vegetable oils used in the industries are glycerides of unsaturated aliphatic acids containing not less than 18 carbon atoms in open chain; the oil from chaulmoogra seeds contains closed ring substances (Barrowcliff and Power, *J. Chem. Soc.*, 1907, 91, 577). The drying oils of animal origin, menhaden and Japanese fish oil, contain the glyceride of clupanodonic acid. Before discussing the catalytic oxidation of oils our knowledge of their complex chemical constitution and the great variety of changes which take place during oxidation will check the tendency to indulge in speculation or to generalise from insufficient data.

This polymerisation is slower than the oxidation. Wolff (*Farben-Zeit.*, 1919, 24, 1119) maintains that in the case of oil varnish on exposure to light of short wave-length oxidation and polymerisation proceed at nearly equal rates, whereas in light of long wave-lengths polymerisation is retarded more than oxidation, with the result that inequality of outer and inner layers occurs, with the production of shrivelled films. Polymerisation is of great importance in consideration of the durability and water-resisting power of oil films. The following table shows the percentage of linoxyn obtained from several forms of drying oils, from which it is evident that the linoxyn produced from a thickened oil is greater in amount and more water-resisting than that obtained from ordinary linseed oil. There is evidence of slight difference between the action of lead and manganese as driers.

With regard to the subsequent changes in the linoxyn there is no consensus of agreement. The possibilities are so many, comprising, in addition to peroxides, acids, aldehyde-acids, substances with definite acetyl value, and volatile products. (See Fahrion, *Chem.-Zeit.*, 1904, 1196; Orloff, *J. Russ. Phys.-Chem. Soc.*, 1910, 42, 658; Fokin, *Z. angew. Chem.*, 1906, 1219; Ingle, *J.*, 1913, 32; 1919, 101; Salway, *J. Chem. Soc.*, 1916, 169, 138; Wilson and Heaven, *J.*, 1912, 565; Waele, *loc. cit.*; Reid, *J.*, 1894, 1020.)

Genthe (*Z. angew. Chem.*, 1906, 19, 2087), in his investigation of the oxidation of linseed oil in

Water absorption of drying oil films after treatment with petroleum spirit and methylated ether.

				Time of drying in days.	Petroleum. 3 Days	Petroleum. 6 Days	34 Days in meth. ether	% Linoxyn.	Water immersion, % gain.			
									1 Day	2 Days	4 Days	8 Days

Mn present								milky		
Linseed oil		12 hrs.	—	—	68.8	31.2	18.0	5 Days		
Pb & Mn present							cloudy	23		

From the general properties of the glycerides it is to be expected that oxidation will proceed in stages whereby a molecule of oxygen becomes attached at a double linkage; such gradual absorption has been observed in the oxidation of China wood oil (Morrell, *J. Chem. Soc.*, 1918, 113, 111).

When linseed oil is transformed into the highly-oxidised state of linoleum the glyceride of diperoxylinolenic acid is found to be present (Waele, *J. Ind. Eng. Chem.*, 1917, 9, 1), and in linoxyn there are still unsaturated linkages. Ingle's formula for linolenin (the triperoxylinolenic acid glyceride) does not appear to be realised in practice, although it may represent the autocatalyst formed in the oxidation of linseed oil without the use of driers. Orloff's formula for linolenin (*J. Russ. Phys.-Chem. Soc.*, 1910, 42, 658), representing an oxido and peroxide is possible, but difficult to verify. The author favours a subsequent or, under certain circumstances, a simultaneous polymerisation of the peroxides in view of the results obtained from the study of the cerium salt of tung oil (*loc. cit.*), and from the recent work of Stobbe and Dunnhaupt (*Ber.*, 1919, 52, 1436) on cyclopentadiene, which is transformed on oxidation into a diperoxide dimeride:

ultra-violet light with and without driers, obtained in the latter case a sinuous form of curve expressing the relationship between the amounts of oxygen absorbed and the time. This form is characteristic of an autocatalytic change (Kullgren, *Z. physik. Chem.*, 1912, 41, 405) and can be expressed by the Ostwald equation for the intervention of an autocatalyst, viz., $\frac{dx}{dt} = k(a-x)(b+x)$, where a is the initial concentration of the oil, b that of the autocatalyst, and x the amount of oil oxidised. It is possible that the autocatalyst is a higher peroxide than that found in linoxyn.

The presence of the siccativ shortens the induction period (*cf.* Rideal, "Catalysis in Theory and Practice," 1919, p. 149). From a comparison of series of metallic driers as arranged by Fokin (*Seifens. Zeit.*, 34, 821) and by Mackey and Ingle (*J.*, 1917, 317), it might appear that the metals which are capable of forming series of oxides prove themselves the best siccatives. Fokin states that polymerisation proceeds parallel with oxidation, and between 0.2 and 20 atm. the oxygen absorption is proportional to the pressure. The velocity is stated to increase with the cube root of the concentration of the catalyst, but it seems not strictly accurate to develop a relationship between the reaction velocity and the concentration of the catalyst added; the superficial concentration ought to be substituted. The metal content of varnishes

stands in no stoichiometric proportion to the mass of the oxidation product, and, according to Weger (Chem. Rev., 1898, 5, 4) the drying power of manganese increases up to 0.2%, further increase in concentration causing no acceleration in drying (cf. Bach, Oxidation of hydriodic acid by hydrogen peroxide in the presence of peroxydase; Ber., 1904, 37, 3798). Lippert (Z. angew. Chem., 1898, 11, 433) states that the combined oxygen is increased by the presence of small quantities of manganese driers, but with increasing amount of drier up to 0.2% the oxygen number falls. It is stated that without driers peroxides tend to be formed, but in the presence of driers atomic oxygen is absorbed. There would appear to be an advantage in the use of mixtures of lead and manganese in the case of the oxidation of linseed oil, and the best proportions are stated to be 5Pb:1Mn up to 0.6%. Ingle (J., 1919, 101 r) states that manganese driers catalyse the transformation of linseed oil into linoxyn four times as rapidly as lead driers. Rochs (Z. angew. Chem., 1911, 34, 80) seeks to explain the difference by the following scheme:—

where manganese acts as a drier, and

where lead acts as a drier. When there is a combination of the two driers a peroxide-glyceride of the Orloff type referred to above would be obtained. Another view is that the second drier acts as a polymerising agent, causing a combination of unsaturated molecules and preventing the oxidation being carried too far, as in the case of Reid's superoxidised oil. The author considers this view worthy of consideration, especially as aluminium as a drier has been found to give better results than lead (Gardner, Circ. 60, Paint and Var. Manufs. Assoc.); moreover, the advantages of lead as a drier are not so manifest when dealing with polymerised or easily polymerised oils.

There is no doubt that it is advisable to check excessive formation of peroxide-glycerides, which are overprone to subsequent decomposition, and the combination of metallic glycerides in this respect may be favourable. Excess of a manganese drier in linseed oil mixings causes surface drying with rivelling. It is sometimes stated that a drier may after a time lose its activity. Undoubtedly driers often cause an increase in viscosity of mixings whereby the setting time is retarded, but there is no definite evidence in the case of varnishes provided the mixing remains clear and there is no precipitation.

The theory of the action of siccatives is not as yet satisfactory. There has been much speculation following on the lines of consideration of homogeneous systems, whereas the drying of oils belongs to the class of heterogeneous systems.

If the theory of intermediate compounds (Engler's) be applied the scheme suggested by Ingle (J., 1916, 454) appears to be plausible:—

or as in the case of cerium tungstate

Lead and cerium here act as direct catalysts to form linoxyn. In autocatalysis without drier it must be assumed that a higher peroxide is formed which is subsequently decomposed (Jorissen, Chem.-Zeit., 1898, 23, 162).

In the presence of water the production of hydrogen peroxide would be accounted for by the formation of Orloff's oxide peroxide glyceride. The influence of moisture on the oxidation of linseed oil and polymerised linseed oil in the presence of driers is discussed by Waele (J., 1920, 49 r), who notes the stability of the peroxides of polymerised linseed oil. He considers that the decomposition of the primarily formed peroxides is initiated by the presence of water and equilibrium conditions, i.e., decomposition *v.* back pressure, are attained by the interpretation of the latter as pressure of water vapour. Gardner (Circular No. 60) states that an atmosphere having a relative humidity of 20°–30° C. gives the best drying conditions. Assuming the intermediate formation of a higher peroxide acting as an intermediate compound (Genthe found that in ultra-violet light as much as 34% oxygen could be absorbed), then Liveing's explanation of the decomposition of hydrogen peroxide in the presence of silver oxide may be applied ("Chemical Equilibrium the Result of the Dissipation of Energy," 1885). It is known that when linseed oil has been boiled without driers it is oxidised very slowly, but its activity is regained when air is blown in. The marked changes of colour in solutions of manganese, cobalt, and cerium driers all indicate a higher degree of oxidation of the metal, but there would seem to be an equilibrium between the state of oxidation of the metal and peroxide of the oil which is only disturbed on exposure to air. It has been observed by the author that cerium varnishes after a time become yellow out of contact with air, marking the presence of ceric salts, and yet there is no loss on drying on exposure to air. Manganese and cobalt liquid driers, which are at first comparatively pale in colour, become permanently dark on being kept even out of contact with the air.

For heterogeneous systems the adsorption view of Faraday (1833) as to catalytic activity being due to adsorption phenomena is most worthy of consideration. In a homogeneous system the reaction is proportional to the concentration of the catalyst, but in a heterogeneous system the reaction velocity will be influenced by the active volume of the catalytic material; moreover the reaction velocity will be governed by the rate of diffusion of the reactants to the surface or the products from the surface as well as by the rate of superficial action; for the mass concentration must be substituted the superficial concentration. Very little is known of the properties of the surfaces of drying oils. Do the metallic driers modify the superficial properties of the drying oils to different degrees according to their drying properties? From the author's observations the interfacial tensions of equivalent strengths of manganese and cobalt linoleates are different from that of lead linoleate dissolved in linseed oil (the strengths of the solutions were 1.3, 1.4, and 4.96% respectively). The interfacial tension of the lead solution to air or nitrogen was lower than that of linseed oil, but manganese and cobalt solutions have a slightly higher surface tension than linseed oil. With solutions of 1/10 concentration the differences are less marked; the diminution in concentration of the manganese and cobalt salts has very little effect on the values of the surface tension, whereas the reduction in the surface tension of lead linoleate is more marked with variation in the concentration. The surface tensions were determined by Morgan's drop method

(J. Amer. Chem. Soc., 1911, 33, 648), and details of the investigation, which is still in hand, will be published later. The drop numbers of the respective oils into water or of water into the oils have been determined, and it was found that the interfacial tension of the lead solution was much greater than that of linseed oil; manganese oil was slightly greater and cobalt oil was less than linseed oil, but the unavoidable presence of alkali in the salt is accountable for the lowering of the interfacial tension. The direct influence of the concentration of the lead salt was again noticeable, likewise the non-influence in the case of manganese (cobalt for the above reason must not be considered without further investigation).^{*} The presence of alkali in the case of the lead salt was proved to be unlikely, because a lead drying oil made without the use of alkali was found to give results of the same order. The above results throw some light on the peculiar behaviour of lead and manganese driers. Lippert (*loc. cit.*) states that above a concentration of 0.2% manganese the oxygen absorbed is reduced with increasing manganese content; the drying power of lead, on the other hand, increases with increasing content. The application of Gibbs' law from the results of the surface tension determinations would favour increasing surface concentration for lead and a slight alteration in surface concentration of manganese or cobalt. The behaviour of a surface containing a lead drying oil to water is well known, and is in keeping with the drop numbers into water. From the brief statement of the results of a preliminary and incomplete investigation, it is evident that the chemical properties of the metals used as driers will not account for their behaviour, and the study of the differences of surface properties is of importance. The diffusion rate of the products of oxidation and polymerisation or of the reactants depends on the viscosity of the layer, so that it is difficult to make a strict comparison of catalysts.

Driers might be considered as promoters adsorbing oxygen selectively at the surface followed by chemical combination.

On an hypothesis of directive and selective adsorption, connexion is made between the intermediate compound theory and the adsorption theory, because the idea of a directive force assumes chemical union between the surface of contact and the molecules of the surrounding medium. The distinctive character of the interfacial molecular condition has been put forward by Langmuir (J. Amer. Chem. Soc., 1918, 40, 1361), who assumes that the solid catalyst becomes coated with a single layer of molecules by adsorption; such condensation is accompanied by a change in the character of the adsorbed molecule involving a dissociation of elementary molecules (*e.g.*, oxygen into atoms), by which the atoms of the condensed substances are definitely associated with certain molecules in the surface layer. The application of Langmuir's theory by Lewis (J. Chem. Soc., 1919, 115, 1821) in terms of the radiation hypothesis involves the consideration of the condensation on the surface of the catalyst in the atomic form.

It is evident that more attention must be paid to the study of the catalytic oxidation of oils from the conditions at the interfacial surface, whereby connexion may be established between the superficial forces and those manifested in the chemical changes which are known to occur during the oxidation and setting of oils.

DISCUSSION.

The CHAIRMAN suggested that the method proposed by Mr. Heaven and himself (J., 1912, 565) might be helpful in regard to the elucidation of the formulæ of Rochs and Ingle; and further, with the reduction of the film to its smallest possible

dimensions, by that method of impregnating kieselguhr possibly some information on the nature of the oxidation by the catalyst might be obtained. The order of activity of the catalysts was very interesting. He had believed that the activity depended upon the fact that they existed in two or more oxide or hydrated forms, and that the activity depended upon the rate of change from one form to the other, this being the rate at which oxygen was transferred. He was doubtful as to the catalytic effect of sodium and calcium.

Dr. E. B. MAXTED said that the surface of separation between the catalyst and the substances which were undergoing reaction on its surface might be regarded from a kinetic standpoint. He thought considerable progress might be made in heterogeneous catalysis generally by considering this surface layer as a zone in which the various possible intermediate compounds and final products were all capable of existence side by side, and in which the actual equilibrium state would be such that there was a definite proportion between these possible intermediate compounds in a kinetic sense only, namely that, while the actual number of molecules of each species in equilibrium remained constant, the individuality of these molecules constantly changed with change in time. It was quite possible to see how cobalt etc. could help the absorption of oxygen by oil, by reason of the fact that among the various possible compounds formed on the surface of separation there would be peroxides in which the oxygen was at a potential sufficient to be transferred to the oil. One other interesting point was the possibility of inhibiting the absorption of oxygen by means of catalyst poisons.

Mr. F. H. ALCOCK asked if the process of oxidation in oils would determine the question of purity and impurity in linseed oil.

Dr. MORRELL, in reply, agreed as to the necessity of considering the question of the oxidation of oil from Dr. Maxted's standpoint, and that a careful examination of what was taking place on the surface was necessary. He had no knowledge of any catalytic poisons in the oxidation. It was stated that certain driers lost their power. In certain cases it had been shown to have been due to the oil or the varnish mixing. There might be deposition of the drier from the solution—such cases were known. The purity of the oil could be decided by the drying oil method. The iodine value determination was always supplemented by a drying oil test.

THE ACCELERATION OF VULCANISATION.

BY D. F. TWISS AND S. A. BRAZIER.

This paper, read by Dr. Twiss, has already been published in the Journal for May 15, p. 125 T.

DISCUSSION.

The CHAIRMAN asked if it was not possible that a certain proportion of the apparent retarding effect of zinc oxide was due to a reaction between the zinc and some of the sulphur at the temperature of vulcanising, which might not occur in the presence of thiocarbanilide?

Dr. SLATER PRICE said that he could not recall having seen any equations for the velocity of a reaction which was auto-catalysed which led to a straight-line curve. It would appear that some other explanations might be given. Straight-line curves were found in various fermentation reactions, for example, in sugar fermentation, and they had been explained by a combination of the sugar and the enzyme, the concentration of this combination remaining practically constant during the reaction.

Dr. MAXTED suggested that if vulcanisation took place between a certain amount of sulphur dissolved in, or associated in some way with the catalyst, it was possible that that might maintain a

^{*} The densities and viscosities of the solutions were determined under the same conditions of temperature.

constant concentration right down to the end of the reaction. Had experiments been made as to the relative vulcanising power of the various solid allotropic forms of sulphur?

The CHAIRMAN pointed out the close parallel in respect of the vulcanisation of rubber and the oxidation of oils. In addition to the combination with sulphur, was not a change in the rubber possible in the direction of polymerisation? In the oxidation of drying oils there was a strong indication of polymerisation occurring at the same time. The degree of polymerisation accompanying combination of the sulphur might probably account for many of the peculiar physical properties of the vulcanised rubber.

Dr. Twiss, in reply, said that he thought the suggestion that the retarding action of zinc oxide might be due to this substance competing with the rubber for the sulphur was improbable. The extent of the combination of zinc oxide and sulphur under the conditions of vulcanisation was not very considerable and as there was only 1% of zinc oxide present in the mixture in question, the actual reduction in the quantity of sulphur through this cause must have been very small. He agreed that zinc oxide itself might exert a very feeble catalytic effect, but the results showed that this substance should then be regarded as a negative rather than as a positive catalyst. As to the suggestion of the intermediate formation of some sulphur compound during the vulcanisation process, analogous to the combination of enzyme and sugar in fermentation, he pointed out that there was evidence of the occurrence of auto-catalysis; this was to be attributed to the influence of some catalytically active body produced by combination of sulphur with some other substance, possibly with one of the natural impurities of the rubber or even part of the rubber itself. Some years ago he had published figures showing that insoluble sulphur had approximately the same vulcanising power as crystalline sulphur. This might be expected in view of the recent evidence of Beckmann that S_8 when heated above the melting point of ordinary sulphur very rapidly became converted into an equilibrium mixture of the same composition as that yielded by S_8 . During the vulcanisation process, therefore, pure sulphur, whatever its original form, would in all probability, be present as the equilibrium mixture corresponding with the temperature. Apart from this, however, the fact that the temperature coefficient was approximately the same at different temperatures indicated that the various allotropic forms present in molten sulphur did not differ greatly in their chemical activity towards rubber. As to the polymerisation of rubber, it was evident that during vulcanisation two processes took place—a chemical process and a physical change induced by the former. The two were not, however, entirely proportional to one another. It had even been suggested that vulcanisation was only a physical process, that the sulphur was practically a catalyst, and that the effect was merely a polymeric change in the rubber itself, but general opinion was contrary to such a view.

other metallic element, and yet, how little we understand concerning the nature of the action of light upon them!

If, as seems most probable, a number of the elements are capable of forming compounds as sensitive to other forms of energy as those of silver are to light, then truly we are but at the beginning of an era of progress which must inevitably lead to undreamt-of additions to our methods of intercommunication and record by means of that wonderful interplay of natural forces of which present-day photography is but one expression.

I do not propose to deal very fully with that part of Hurter's researches for which he and his colleague, V. C. Driffield, are perhaps chiefly remembered by photographers; the avowed primary object of their work was the very practical one of discovering a scientific method of speed determination which would lead to the elimination of waste by incorrect exposure on the part of the user and to scientific control of the industrial preparation of dry plates. This purpose they undoubtedly achieved in so far as any one numerical value can express the light-sensitiveness of a material which is capable of such wide variations of character.

The mere invention of a practical method of determining and expressing the light-sensitiveness of a plate would, however, never have given Dr. Hurter that niche in the Temple of Fame which he justly occupies if it had not been a system which contained within itself the capacity of adaptation to the needs of later workers and different circumstances and had it not been built on a sound scientific foundation.

It is true that the serious, if not insurmountable, difficulties of standardising the conditions of speed testing throughout the industry, the comparatively wide variations in the shape of characteristic curves of commercially useful dry plates, and the proved unsuitability of the true H and D speed number alone as a guide to exposure in certain important branches of photography (not to mention the baneful influence of commercial advertising), have all contributed to cause published speed numbers to be regarded with considerable distrust. Nevertheless it is literally true to say that the Hurter and Driffield characteristic curve is, and will doubtless remain, the most compact and lucid means of expressing quantitatively the qualities of any and every light-sensitive material.

Prior to the work of Dr. Hurter and his colleague it was fairly generally believed that a gelatin dry plate resembled the wet collodion plate in being capable of development to any desired extent if plied with fresh developer, subject only to the practical limitation that general fog supervenes after a more or less short time. Indeed, this view was prevalent for many years, and is probably not yet entirely extinct. Hurter and Driffield showed conclusively, however, that such is not the case, but that for any given plate the limit of possible development is set by the amount of change wrought by the exposure.²

We know now that the reason for this lies in the fact that the silver halide grain behaves as a self-contained unit. These units are by no means all alike³; those grains which have been sufficiently exposed are reducible, while the less exposed ones, which remain unreduced, apparently play little or no part in the normal development process.⁴ Further, we know that the silver halide grains in commercial dry plates vary both in size and in light-sensitiveness.

It is, however, highly desirable that a thorough study should be made of the behaviour of the individual grains in the exposure and development processes to determine:—

(a) The minimum exposures required to make them developable.

(b) The range of sensitiveness to be found among the grains in a few typical emulsions.

Liverpool Section.

Meeting held on May 27, 1920.

DR. E. F. ARMSTRONG IN THE CHAIR.

PHOTOGRAPHIC IMAGES—VISIBLE AND INVISIBLE.

BY F. F. RENWICK, A.C.O.I., F.I.C.

(HURTER MEMORIAL LECTURE.)

The chemistry of silver and its salts has probably been more closely studied than that of almost any

(c) The connexion, if any, between size of grain and light-sensitiveness.

(d) Whether, as seems probable, the rate of reduction of a given quality of grain with a given developer increases to a maximum at a certain exposure before it declines again almost to zero.

Naturally such a research is beset with numerous difficulties, but Kinoshita's⁴ work under Rutherford, at Manchester, on the behaviour of photographic plates to alpha particles shows that they are not insuperable.

At present we merely know from a comparative study of the characteristic curves of different emulsions that the position and shape of the curve of any plate is influenced by the range of sizes and sensitiveness of the grains and their relative proportions⁵ in the emulsion, the extent to which development is carried, as determined by the developing solution employed, its temperature and time of action, and its rate of absorption by and diffusion in and out of the gelatin film⁶; and, lastly, there enter into the final result the extremely complicated optical problems which arise when dealing with the penetration of light through turbid media.⁷

Hurter and Driffeld,⁸ Schaum, and many other investigators have assumed that the amount of developed silver in a negative is a reliable index of the amount of photo-product formed during exposure, but that this is not at all accurately the case has been known for some time, and is strikingly brought out by some experiments carried out last year at the Ilford Laboratories.

A gelatin emulsion in the liquid state was divided into two parts, and one of them was fogged by light while it was thoroughly stirred. Mixtures in known proportions of the light-fogged and of the clean unfogged emulsion were then made and coated equally heavily on a number of test plates. In this way we were able to secure plates having known relative amounts of latent image per unit area. After careful drying, plates of each mixture were developed together, fixed, and dried and their densities measured. Fig. 1 shows the results in graphic form of a typical experiment. Abscissæ represent the relative proportions of fogged emulsion (=latent image \times constant) actually present, the ordinates give the densities developed in various times. If it was not so before, it will already be

Fig. 1.

evident how complex are the factors which contribute to determine the qualities of a photographic dry plate; fortunately, it is rapidly becoming more clearly recognised that new methods of attack must be devised to enable us to separate one influence from another and so arrive at fundamental truths.

In connexion with the developed plate there is another interesting and important problem—

namely, that of tracing the connexion between the size of the emulsion grain and that of the developed silver grain. It is well known that the latter are, on the average, larger, more irregular in outline than, and somewhat differently distributed from, the original emulsion grains. While emulsions of large-sized grains always give coarser-grained negatives than fine-grained emulsions, there is very little likeness in size or shape between them in the dry negative. Lüppo-Cramer⁹ has, however, shown that the silver deposited in the process of development is in the semi-fluid condition of a colloidal silver-gel, and, as he suggests, it is therefore probable that the cavities and channels in the spongy matrix (caused by solution of the haloid during development and fixation) help to determine the forms of the silver grains and their distribution in the finished negative.

From this brief survey of some of the factors influencing the shape of the Hurter and Driffeld characteristic curve we may turn to a consideration of some of the more chemical aspects of the subject.

Dr. Hurter's consideration¹⁰ of the properties of the latent image led him to believe that the first action of light on silver bromide induced only a physical change and not the formation of a new chemical product. It is interesting to note that in English-speaking countries those aspects of the matter which weighed most strongly with Hurter have usually been prominently borne in mind, while continental photo-chemists have tended in many cases to ignore these difficulties and to seek an explanation of a purely chemical character.

It would take far too long, nor would it be entirely profitable, to examine critically the many explanations of photographic action which have from time to time been offered.¹¹

They divide themselves into two broad classes. Firstly, those which seek to explain all photographic action as chemical change in which one or more new products are formed by the direct action of light. Secondly, those which maintain that, although when *visible* photographic images are formed, chemical change must be admitted, this is not the case in the earlier stages where a development process is essential to make the photographic action apparent.

This division of opinion dates from the early days of photography and still persists as strongly as ever. Meldola credits Fischer with having first suggested a subchloride theory as early as 1814, while direct reduction to metallic silver was offered as the explanation by Arago as early as 1839. On the other hand, Moser, in 1842, and Claudet, in 1848, both held strongly that the latent image was the result of a purely physical change. Subsalt theories were, or are still, advocated by Eder, Schaum, Trivelli, Vogel, Carey Lea, Abney, and many others; reduction to silver is the theory favoured by R. Abegg, R. Luther, W. Reinders, R. Lorenz, R. Zsigmondy, E. Baur, and Lüppo-Cramer.

The only physical change theory which now has many supporters concerns itself with changes in electrical condition brought about by the action of light on the silver halides, though many other more or less vague kinds of physical change have been advanced as explanations in the past and are still advocated by a few.¹²

Electrical theories¹³ of the latent image are relatively new and naturally are fashionable in these days of electrons and photo-electricity. It remains to be seen, however, whether they will prove more helpful in advancing photography than other physical change hypotheses have been. Even if the two chief chemical theories were finally disproved it would still have to be admitted that both have borne valuable fruit by giving rise to much experimental research of the highest value.

The point at issue really lies in the answer to the question: Does the smallest demonstrable light

effect coincide with the formation of a new chemical substance, and, if so, what is its nature?

It will be evident that ultimately everything turns on our interpretation of experiments concerning the persistence or destructibility of the *developable condition*, since this is our only evidence for the existence of something which we call a latent image. Chemical development is a catalytic reaction in which the normal speed of reduction of unexposed silver halides by reducing agents of a certain kind (which is a slow reaction when the silver halide is embedded in a colloid medium) is enormously accelerated by traces of this mysterious photo-product in the light-affected salt. Destruction of the latent image (*i.e.*, loss of the developable condition) does not therefore necessarily imply the removal (by solution or chemical combination) of a chemical substance, any more than the "poisoning" of a sample of platinum black by arsenic means that platinum is no longer present when it fails to activate certain well-known chemical reactions. It should also be borne in mind that while silver readily acts as a nucleus for the deposition of more silver from the developing solution itself in the so-called physical development process, the fact that a photographic image can be built up in silver by means of such a physical developer offers little indication as to the chemical character of the original nucleus which we call the latent image, for such solutions precipitate silver on all kinds of surfaces very readily. When, therefore, I use the term "latent image" it should be understood that I really mean the "developable condition," and I admit that this condition may not always be due to the catalyst originally present which was formed by the action of light.

The present paper will be confined mainly to a consideration of three only of the ascertained properties of the latent image: Firstly, the possibility of physically developing an image on a fixed and washed plate; secondly, the possibility of transferring and subsequently developing (both physically and chemically) latent images from the silver salt in which they are formed to another, by changing the former chemically into a less soluble silver salt; thirdly, the destructibility of the latent image by the further action of light itself under certain conditions.

The possibility of physically developing the latent image on an exposed and fixed collodion plate was discovered in 1858 by Young,¹⁴ and then further investigated by Davanne in the following year. In 1895 Kogelmann¹⁵ discovered that gelatino-bromide of silver emulsions behaved in the same way. Further work on the subject by Sterry,¹⁶ Neuhauss, and Lumière and Seyewetz have improved the technique of the process very materially. Moreover, it has been shown that a number of other fixing agents may replace the usual solution of sodium thiosulphate with similar success.

Such experiments constitute one of the strongest pieces of evidence for the material rather than the electrical character of the latent image.

Unfortunately, while physical development entails very little more exposure in the case of very fine grained slow plates, when plates of high speed, coated with what are known as ripened emulsions of silver bromide in gelatin, are employed, it is usually necessary to give at least ten times the normal exposure necessary for alkaline development to get a complete picture. Hence such experiments fail to give evidence in favour of the existence of a newly formed chemical substance in the least exposed parts of a normally exposed rapid dry plate.

The transference of latent images from one silver salt to another has scarcely received the consideration it deserves in connection with studies of the latent image.

In 1881 Eder and Pizzighelli¹⁷ showed that an exposed silver chloride plate could be converted by

treatment with potassium bromide into silver bromide without any loss of the developable condition.

In 1887 Carey Lea¹⁸ showed similarly that light-affected citrate, benzoate, tartrate, and pyrophosphate of silver gave developable silver chloride or bromide after treatment with dilute hydrochloric or hydrobromic acid, even when followed, after a thorough washing, by treatment with dilute nitric acid. Some advocates of physical change theories of the latent image have sought to account for these results by saying that the physically changed condition produced by light is transferred to the newly formed halide in the course of the reaction.¹⁹ This explanation, in the absence of knowledge as to the nature of the first change, explains nothing.

In attempting to apply the method of image transference to rapid gelatin dry plates we are met with the difficulty that only the iodide and sulphide of silver are less soluble than the bromide, and alkali iodides have long been known to have a powerful effect in preventing development. It has been repeatedly stated that they rapidly destroy the latent image. (Dr. Hurter²⁰ himself makes the statement, and uses it as a powerful argument in favour of a physical change theory of the latent image.) Others have affirmed the contrary.²¹

On considering the matter it appeared probable that the loss of the developable condition observed on treating a dry plate with a solution of an alkali iodide might arise from two causes. Firstly, to the known tendency of the alkali iodides to hydrolyse and behave in certain reactions as if they contained free iodine, and secondly to the great capacity of silver iodide for adsorbing soluble iodides, which would very much increase the difficulty of reducing it to metallic silver by alkaline development. To subdue as far as possible the former tendency it is desirable to add a neutral sulphite to the iodide solution employed in any such experiments.

In some recent experiments I have been able completely to fix out exposed gelatin dry plates in two or more changes of strong solution (20%) of potassium iodide containing 5% of (cryst.) normal sodium sulphite and, after well washing out the iodides with a weak (2%) normal sulphite solution, to develop the fully exposed parts in the Lumière and Seyewetz physical developer (silver sulphite and *p*-phenylenediamine). The loss of the image in the less exposed parts even with slow plates is, however, considerably more than when a neutral thiosulphate solution containing sulphite is employed.

The gelatin coating of most plates will not withstand prolonged treatment with 20% iodide solutions without softening badly or even dissolving, and it soon became clear that part of the loss of developable image was attributable to its mechanical removal with the more soluble constituents of the gelatin itself.

This was confirmed by the observation that a preliminary toughening of the gelatin in a weak formalin bath before fixation was advantageous with all fixing agents, and particularly so with strong iodide solutions. These experiments showed that iodides, even in very strong solutions, certainly do not destroy the latent image completely. Unfortunately they throw practically no further light on the question of the nature of the photo-product, and furnish no evidence whatever as to the effects of minimum exposures.

In 1891 Lainer²² discovered that extremely weak iodine tincture when added to certain of the less energetic alkaline developers considerably augmented the amount of image which could be developed for a given exposure. Interesting studies of this remarkable action of soluble iodides have since been made by v. Hübl,²³ Lüppo-Cramer, and others in which the extremely weak iodide solutions employed were sometimes applied to the plate before development, but no systematic attempt appears

to have been made to study the effect of completely converting all the silver salts present into iodide before development, by means of longer bathing and stronger iodide solutions. The effects produced by extremely dilute solutions are very remarkable, and are undoubtedly important for any student of the latent image problem, quite apart from their practical applications. They appear to me to be best explained by Lüppo-Cramer's suggestion that an appreciable part of the latent image is situated within the crystalline silver halide grain, and is only brought into play by the disruptive processes consequent on the rapid conversion of the surface of the grain into silver iodide or by the use of the most energetic developers. It should also be borne in mind that the alteration of the size and distribution of the substance of the grain which partial conversion to iodide must entail is also likely to affect the bulk, the distribution, and the composition of the reduced silver and unreduced silver iodide²⁴ and sulphide of which the negative grains are usually composed.

When, however, the iodide solutions used convert the whole of the silver bromide into iodide, but are not strong enough to fix the plate, the results hitherto obtained have lent strong support to the supposition that the latent image is to a considerable degree destroyed by iodides.

Five or six minutes' immersion in a 1% solution of sodium or potassium iodide containing 2-3% of a normal sulphite is sufficient to convert all the silver salts into iodide if the solution is kept moving over the face of the plate unless the emulsion coating is unusually heavy. Washing after conversion into iodide should be carried out with a dilute neutral sulphite solution, and development is fairly rapid in a solution containing about 1% of amidol and 10% each of crystallised sodium sulphite and carbonate. Owing to the insensitiveness of silver iodide when precipitated in presence of excess of a soluble iodide, it is possible to develop plates after the iodising process is complete in a strong white light. Of course, should any part of the original bromide remain unconverted to iodide it will be fogged and blacken immediately in the developer, while even in a dark-room any unchanged bromide fogs badly in a few minutes in alkaline amidol, so that unchanged patches, if present, are readily detected.

Some time after I had first succeeded in making negatives in artificial white light in this manner I found that a patent had been taken out in Germany by R. Freund²⁵ for a process of developing plates in weak daylight after treating them with a 4% solution of potassium iodide followed by a rinse in water before development. I can only say that in

Fig. 2.

Some recent experiments made in the Ilford laboratories have demonstrated, however, that it is possible to "transfer" the latent image from both slow and rapid plates to silver iodide with very little loss indeed, and that such "iodised" plates may be satisfactorily developed either by means of the Lumière and Seyewetz physical developer or chemically by means of solutions of amidol in sulphite and alkali carbonate.

the light of my experiments I am not surprised he did not develop his process to a successful issue. I do not, however, anticipate that the possibility of developing negatives in artificial light will induce photographers to abandon the use of a dark-room for this part of the process of negative-making unless the serious disadvantages apparently inherent in the method can be removed. The chief objections are (1) that some increase of exposure is usually

necessary, though this does not amount to more than two- to three-fold under the best conditions; (2) that the iodising treatment must be carried out in some form of dark chamber; (3) that the highly poisonous cyanide fixing bath is almost essential to dissolve the undeveloped silver iodide in a reasonably short time. There is also a fourth difficulty which I will mention shortly. But for these drawbacks the process would be most useful for developing panchromatic plates.

The diagrams given in Fig. 2 show in the form of characteristic curves some of the results obtained in the Ilford laboratories for a range of sensitive negative materials.

When the silver bromide of a dry plate is converted to iodide the clear, sharp-edged crystals of which the emulsion grains consist are completely changed in character. They lose their crispness of outline, and apparently become a more or less confused aggregate of either amorphous or micro-crystalline silver iodide, as the accompanying photomicrograph shows (Fig. 3). It is therefore not surprising, in view of what I mentioned earlier concerning the influence of grain size on the shape

it is still capable of exercising its powerful catalytic influence in the developing process. That less of the latent image is lost in this process than by fixation followed by physical development is, I believe, due to the partial blocking of the pores of the gelatin by the new halide as it replaces that originally present.

The last reaction of the latent image to which I wish to direct attention is its light-sensitiveness.

The best known and most discussed evidence of this is embodied in numerous very conflicting studies of the phenomena of so-called reversal or solarisation. The most thorough investigation of these phenomena is, I believe, due to Volmer²⁶ and Schaum, but as these effects are notoriously complex and refer to conditions under which chemical change has certainly already begun, I do not propose to discuss them here.

It has, however, long been known that it is easy to demonstrate the light-sensitiveness of the latent image in its early stages under certain conditions.

In 1859 Poitevin²⁷ discovered that if a collodion wet plate be uniformly fogged, then washed to remove the excess of silver nitrate and subsequently

1 small scale division = 1.3μ (thousandths of a millimetre).

Natural emulsion grains.

After conversion to iodide.

Fig. 3

of the characteristic curve, to find that those derived from iodised plates often differ somewhat markedly in character from the characteristic curves of the original dry plates employed. An interesting new field of research is open to exploration in the comparative study of the characteristic curves of "transferred" latent images after development. Such "iodised" plates also respond very well to physical development in Lumière and Seyewetz' silver sulphite and *p*-phenylenediamine developer, giving clear negatives with much more detail than can be obtained from a given exposure after fixation in weak sodium thiosulphate. In all cases the developed plates should be fixed in a weak (2%) solution of potassium or sodium cyanide containing 2% of crystallised normal sodium sulphite, and it is preferable to add a little sulphite to the first few changes of water during the final washing process.

I am of opinion that image transference should be regarded as fixation before development, followed by precipitation *in situ* of another silver salt in place of that dissolved. The photo-product, whether it be modified or not, is not chemically destroyed, but clothed anew in a garment of freshly precipitated and less soluble silver halide on which

immersed in a bath of potassium iodide, then, on exposure in the camera the latent image originally formed is destroyed where the light has fallen on the plate. It therefore becomes possible, after another wash to remove the excess of soluble iodide, to develop a positive picture by means of the usual acid ferrous sulphate (or pyrogallol) and silver nitrate developer. This remarkable reversing action of light on the latent image in the presence of soluble iodides I have recently been able to obtain quite easily with gelatin plates and alkaline development.²⁸ It suffices to give an ordinary negative plate such an exposure to diffuse light as could be developed to a good density in a pyro-soda developer, then to bathe the plate in a weak iodide and sulphite solution till completely converted to silver iodide, and expose the still wet plate behind a transparency. After a brief wash, the plate will develop in alkaline amidol giving a positive copy of the original.

I have also succeeded in making fairly good direct positives in the camera with exposures of 5 to 15 minutes at F8 in a well-lighted studio. (The slide shown is one of the best of them.)

On making an exposure in a spectrograph it was extremely interesting to find that the reversing

rays are restricted almost entirely to a narrow band in the blue of the spectrum lying between 0.43 and 0.48 μ with a sharp maximum at 0.45 μ , as Fig. 4 shows.

Fig. 4.

I particularly wish to emphasize the fact that this reversal will take place perfectly well in the presence of neutral sulphites, thiosulphates, and other halogen-absorbing reagents, conditions under which the liberation of free iodine would appear to be most improbable.

Thiosulphates act as powerful sensitizers in this reversal process, and it is therefore interesting to notice Carey Lea's observation²⁰ that the conversion of gold-coloured allotropic silver to the crystalline intermediate form was accelerated by traces of (hyposulphite?) impurity in the paper it was coated on.

One of the best iodising solutions for reversal effects on negative plates consists of 1 g. sodium iodide, 2 g. cryst. sodium sulphite, 2—4 g. cryst. sodium thiosulphate, 100 c.c. water.

It will at once be seen that the possibility of developing in white light plates which have been iodised after exposure is therefore subject to the further drawback that most of the iodising solution must be removed by washing before light is admitted to the plate, otherwise a serious loss of image may result, though the addition of thio-cyanates to the iodising bath diminishes this tendency. Nor does it appear likely that the direct production of positives in the camera will prove more successful as a practical process on gelatin plates and by chemical development than did Poitevin's original discovery. Both processes, however, are of the greatest scientific interest in their bearing on the problem of the nature of the latent image.

It must, I think, be admitted that many phenomena, and particularly those connected with physical development after fixation and the transference of latent images from one silver salt to another, speak strongly against the view that the latent image is due to a purely physical alteration, electrical or otherwise, of the silver salt. If, then, we must conclude that the latent image is a substance present in excessively minute amount, we are driven to ask what is its nature?

All attempts to prepare true subsalts of silver have failed, except in the case of Guntz' subfluoride,²⁶ and even that is challenged by Vanino and Sachs.²¹ Moreover, the work of a long line of investigators,²² terminating with K. Siehling and W. Reinders, seems to prove conclusively that the photosalts of Carey Lea, which he regarded as lake-like complexes of a subsalt and normal halide, are really solid solutions of colloidal silver in silver halide. Hence it would appear on chemical grounds that the product of light action must be silver rather than a subhalide. One cannot fail to be impressed by the extreme readiness with which silver in the colloidal or even in the finely-divided metallic state goes into solid solution in silver chloride and bromide, and by the great resistance offered by some of these solid solutions to attack by silver solvents and to complete reduction by reducing agents.

All chemical change theories of the latent image have constantly been challenged on the ground that

the amount of energy available in the light required to produce a developable image is totally inadequate to overcome the chemical affinity of the silver for the halogen atom. In its most concrete and recent form this challenge is reiterated by Mees,²³ on the authority of P. G. Nutting.

Consideration of the statement, however, seems to show that it proves too much, for it claims "that it is quite certain what happens when the latent image is produced by a minimum exposure to light, and that the change is really the unit change that can be suffered by any substance when acted on by energy"; in this case, the loss of one electron per silver bromide grain.

It is to be noted, however, that the figures given indicate that the amount of energy capable of producing the first developable impression on a rapid photographic plate must be less than one five hundredth part, and probably nearer one five thousandth of that stated to be required to liberate one electron from a gas molecule.

If, owing to this discrepancy, we must assume that an electron can be so much more easily detached from a solid particle of silver bromide than from a gas molecule, I see no reason why one may not justifiably assume the same to be true for the detachment of one or a few atoms of bromine per particle, especially if the silver bromide grain is embedded in a medium capable of uniting chemically with bromine.

I confess, however, that while such an assumption may be legitimate, I do not consider it entirely satisfactory as an explanation of the beginnings of photographic change in our modern highly-sensitive emulsions. The fact that very sensitive emulsions can be prepared in colloidal silicic acid tells against it, as does also the inability of powerful halogen absorbents to enhance speed when added to an emulsion, although, as is well known, some of them are very effective in inhibiting reversal.

It is much to be regretted that the photographic researches of Carey Lea, and especially his classic papers on the photosalts and the colloidal forms of silver,²⁴ have not been re-published in book form in this country, as they have in Germany, and hence remain largely unknown to the British photographic industry. Much study has been devoted to these extraordinary materials in Germany and Holland, and there can, I think, be no doubt that the work of Reinders²⁵ in particular is the most important contribution of this century towards a solution of the latent image problem.

Carey Lea showed that there is an almost infinite variety of these photosalts, differing in colour, in resistance to oxidising agents, and in light-sensitiveness. He showed that a pale pink form of photochloride containing only a fraction of 1% of dissolved colloidal silver is far more light-sensitive than the normal colourless salt, and that the golden coloured and other forms of colloidal silver ultimately revert to ordinary white (metallic) silver both on exposure to light and on friction.

Reinders has carried the matter still further by preparing solid solutions of colloidal silver in well crystallised specimens of silver chloride, and by showing that some of them are very much more light-sensitive than normal silver chloride, and that when these crystals darken in the light they do so right through the body of the crystal. He also records numerous other interesting observations, such as, that while solid solutions of gelatin in silver chloride raise the light-sensitiveness of the latter very appreciably, a cream coloured solid solution of colloidal silver in silver chloride is still more sensitive; further, that the amount of colloidal silver taken up by silver chloride during crystallisation from ammonia is a maximum in the absence of gelatin, and rapidly decreases in its presence until, with moderate concentrations, quite colourless crystals are obtained even from dark solutions rich in colloidal silver.

It should also be mentioned that R. Lorenz and K. Hiege³⁵ have shown that when clear silver chloride and bromide crystals darken in light, the first effect is the production of a fog or general greying, which later on becomes recognisable under the ultra-microscope as minute particles distributed over the crystal surfaces. These gradually coalesce to form relatively large, dark aggregates of metallic silver with clear interspaces. On these and other earlier observations they advanced the opinion that the latent image is due to colloidal silver in ultra-microscopic form, a view now held by many³⁶ of the supporters of the silver germ theory revived by Abegg³⁷ in 1899.

It is, however, a fact that considerable quantities of colloidal silver solutions (collargol) can be added during the process of making a photographic emulsion without causing any harmful fogging effects, unless the silver is precipitated on the silver bromide grains by addition of acids or other reagent.³⁸

Consideration of these and other aspects of the problem have led me to the conclusion that in our most highly-sensitive photographic plates we are dealing with crystalline silver bromide in which, besides gelatin, some highly unstable form of colloidal silver exists in solid solution, and that it is this dissolved silver which first undergoes change on exposure to light. If this be so, it is clear that it is the function of the ripening process to produce this colloidal silver in the grains of the emulsion in the most sensitive (resonant) form, while avoiding any means which might bring about its precipitation in the gel form—the gel or electrically neutral form of colloidal silver being regarded as the germ or catalyst required to promote development.

J. M. Eder's observations³⁹ on the colour-sensitising action of colloidal silver on silver chloride and bromide serve to remind us of the hitherto unexplained phenomenon that ordinary gelatinbromide emulsions frequently possess a slight sensitiveness to red rays⁴⁰ (sometimes extending through the yellow into the green) at some stage of their preparation. It appears natural to suppose that this colour-sensitiveness is also due to colloidal silver.

Moreover, Carey Lea⁴¹ has shown that some forms of soluble colloidal silver may be restored to the soluble peptised condition by contact with certain salt solutions; it appears possible therefore to offer a reasonable explanation of solarisation by assuming a peptising action on the part of the later-formed chemical products of light action (bromine, hydrobromic acid, etc.) with formation of a photohalide relatively rich in dissolved silver, but almost undevelopable. This suggestion appears to be supported by Carey Lea's observations on the action of nitrites, which are known to inhibit reversal, since he found them to give an insoluble (non-peptisable) form of silver gel. That soluble iodides have a solvent action on silver in the light is fairly obvious from the old direct-positive printing process,⁴² using sun-darkened silver chloride paper after bathing it in a soluble iodide.

Eder's work on the action of nitric⁴³ acid and Sterry's⁴⁴ work on the action of chromic acid on the latent image both seem capable of a complete explanation on the assumption that only true solutions of colloidal silver in silver halide (photosalts) remain after such treatment, and that these are reducible with difficulty by developers. Again, E. Albert⁴⁵ found that if, after giving an exposure to a plate coated with a collodion emulsion, it is treated with a silver solvent (e.g., nitric or chromic acid), then washed and re-exposed to diffused light, a reversed (positive) picture is obtained on development. This experiment also becomes intelligible if we assume that no free silver but only a difficultly reducible and relatively insensitive photosalt remains

in the first exposed areas after treatment with chromic acid.

Such an hypothesis as I have put forward, while it does not throw much light on the why and wherefore of our highly empirical manufacturing processes, seems to offer a more intelligible explanation of the early part of the photographic process than any current theory of the latent image, without calling for any modification of the best supported explanation of the later stages of light action.

It has the merit of reconciling the views of those who demand merely a physical change, those who require the formation of free silver, or a material chemically different from those initially present, to act as a nucleus for development, and it should also meet with the approval of the exponents of the electron theory, since it is apparently well established that colloidal solutions of silver are negatively charged and are precipitated when the charge is lost.

MR. JOHN ALLAN IN THE CHAIR.

THE NEUTRAL HYDROLYSIS OF GUNCOTTON, WITH A NOTE ON THE ALKALINE HYDROLYSIS OF GUNCOTTON.

BY PROF. E. KNECHT AND CAPT. B. R. BOSTOCK.

It is well known that nitrated cotton possesses a pronounced affinity for basic colours, and that it can be dyed with these without the aid of a mordant, but up to now no satisfactory explanation of these phenomena has been advanced. About the year 1902 an attempt was made by one of the authors to ascertain whether a soluble substance could be isolated from guncotton or its decomposition products which would precipitate the basic colours from their aqueous solutions; nothing of the kind could be obtained from the solution of guncotton in boiling caustic soda, but by effecting the hydrolysis of guncotton with cold caustic soda a solution was obtained from which acids threw down a copious white precipitate which on washing and drying yielded a white powder. This substance is somewhat soluble in water, and the solution thus obtained yielded coloured precipitates with basic colours, a property which is shown by one of the products of the alkaline hydrolysis of wool.

Since wool, when heated under pressure with water has been found to yield a product which showed properties in regard to dyestuffs similar to the properties of one of those obtained by its alkali-

line hydrolysis, it was thought that guncotton might behave in an analogous manner. Although a solution was obtained by heating guncotton with water under pressure it was not found possible to isolate from this any substance capable of precipitating basic colours. The primary object of the experiment had thus failed, but it was thought that as guncotton had not been previously completely hydrolysed by water the results obtained might be of some interest.

Silberrad and Farmer (J. Chem. Soc., 1906, 1182) have made an elaborate investigation into the action of water on guncotton at 5-4-4° C. Exposure to the action of water at this temperature was allowed to proceed for 23 weeks, after which a marked deterioration had set in. The decomposition products which had gone into solution were found to consist of nitrous, nitric, formic, butyric, dihydroxybutyric, oxalic, tartaric, isosaccharinic, and hydroxypyruvic acids. Carbohydrates were also found by the fermentation test. The residue consisted of unchanged nitrocellulose.

In our first experiment a small quantity of guncotton was heated for $\frac{1}{2}$ hr. in a sealed tube with water to 200° C. On examining the tube it was found that there was considerable pressure, and that the guncotton had entirely disappeared. The water was of a brownish colour and contained a little charred organic matter, the solution smelling strongly of caramel. Further experiments were conducted on guncotton prepared from pure acids and bleached cotton wool. The product contained 13.05% N. To ascertain the temperature at which complete hydrolysis is effected, sealed tubes, each containing 0.5 g. of guncotton and 25 c.c. of water were heated for $\frac{1}{2}$ hr. in a cannon furnace to 150°, 160°, 170°, 180°, 185°, and 190° C. Only in the last case was any action noticeable, but in this one the guncotton had entirely disappeared, leaving a pale straw-coloured liquid. It was eventually found that a difference of only 2° C. made all the difference between extremely rapid and extremely slow hydrolysis. The rate of hydrolysis and the temperature at which it occurs can be accurately observed by conducting the experiment in a sealed capillary tube containing water, the operation being carried out in practically the same way as the determination of a melting point. It was found that if the temperature was increased even 10°—15° C. beyond 190° a considerable amount of charring took place. Consequently we kept as near to 190° C. as possible in carrying out the hydrolysis for the further work detailed below. The amount of water relative to the amount of guncotton appears to have some influence on the rate of hydrolysis. Two tubes each containing 25 c.c. of water but one charged with 0.5 g. and the other with 1 g. of guncotton, were heated side by side in a cannon furnace to 190° C. In the first case hydrolysis was complete in $\frac{1}{2}$ hr., but in the second over an hour was required before complete solution occurred.

The volume of gas given off from 0.5 g. of guncotton on heating for $\frac{1}{2}$ hr. with 25 c.c. of water to 190° C., collected and measured at atmospheric pressure, was 99 c.c., the same result being obtained in several successive experiments. The amount of guncotton used for collecting the gas for examination was 0.3 g., and in these cases the tubes were completely evacuated before sealing off. After heating in the cannon the gases were drawn off under vacuum. It was found that under these conditions there was not always the same uniformity in volume as in the previous experiments, in which the gases were drawn off under atmospheric pressure, under which circumstances most of the nitrous oxide would remain dissolved in the water.

The gases were analysed in a Bone and Wheeler gas analysis apparatus and gave the following results:—

No. 1 sample of guncotton.—This was carried out

in duplicate. In each case exactly 80 c.c. of gas was obtained having the following composition:—

	(1)	(2)
CO ₂	64.87%	64.9%
N ₂ O	22.37 ..	22.4 ..
CO	3.0 ..	3.0 ..
N ₂	9.75 ..	9.75 ..

No. 2 sample of guncotton.—The gas given off in this case amounted to 87.5 c.c., and contained CO₂ 64.7, N₂O 20.5, CO 5.7, N₂ 9.1%.

There would thus appear to be a considerable discrepancy between the two samples. If, however, the amounts of N₂O and N₂ obtained are calculated on the volumes of the gas evolved it will be seen that they are very nearly the same in both cases. The increased volume obtained from No. 2 sample was made up of CO₂ and CO.

The amount of nitrogen thus found was equal to 10.25% of the weight of the guncotton, and it appeared to be of interest to ascertain the disposition of the remaining 2.8%. An examination of the solutions obtained showed the presence of hydrocyanic acid, ammonia, formic acid, tartaric acid, hydroxypyruvic acid, nitric acid, and traces of nitrous acid.

On heating three separate tubes, each containing 0.5 g. of guncotton and respectively 25 c.c. of (a) dilute caustic soda, (b) dilute sulphuric acid, and (c) water, the amounts of gas formed were: (a) Nil, (b) 126 c.c., and (c) 100 c.c. Hydrocyanic acid was formed only in the last case, viz., by heating with water. The amount of hydrocyanic acid formed was not inconsiderable—in fact, its presence was easily detected by smell and by the formation of a considerable amount of Prussian blue on applying the ordinary test for cyanides. The following estimations were made on the solution obtained in each case from 30 g. of guncotton hydrolysed in an autoclave at 190° C.

	% N as HCN.	
	In distillates.	In residual solutions.
(1)	0.176	—
(2)	0.242	—
(3)	0.211	0.216
(4)	0.216	0.216
Average	0.210	0.216

The total percentage of nitrogen obtained in the form of hydrocyanic acid was thus 0.426%.

The appearance of hydrocyanic acid as one of the products of hydrolysis may seem remarkable at first sight, but in view of L. Henry's statement that nitro-lactic acid decomposes spontaneously according to the equation

into hydrocyanic and oxalic acids (Ber., 12, 1837), the possibility of its formation is by no means ruled out. It is not suggested that in this case nitro-lactic acid is formed as an intermediate product; indeed, the absence of oxalic acid from the decomposition products would indicate that this was not the case. But the formation of some intermediate nitrate which behaves in an analogous manner is not excluded.

The formation of hydrocyanic acid as one of the products of hydrolysis may possibly account for several of our results. In the first place, it is well known that this substance is transformed under favourable conditions into ammonium formate, and this would account for the presence of ammonia in the solution. The presence of ammonia would also account for the observation that nitrous acid could only be detected in traces in the decomposition products. It will also be noticed that the amounts of hydrocyanic acid and ammonia found in the solution varied somewhat in each individual experiment, although the conditions as far as time, temperature, and amount of water to guncotton were concerned were kept as constant as possible.

The estimation of the ammonia was effected in two ways, viz., by the Nessler process and by the

formaldehyde process. Before using the latter process it was first ascertained that none of the constituents remaining in the solution after boiling with a known volume of N/10 sulphuric acid had any effect on the accuracy of the process.

The following results were obtained, a separate hydrolysis of 0.5 g. being carried out for each estimation. The figures represent the ammonia found in percentages of nitrogen: By Nessler process, 1.20%; by formaldehyde process, 1.08, 1.32, 1.19%; average, 1.20%.

The total nitrogen in the solution estimated by the Kjeldahl process was found to be 1.59%. Subtracting from this the nitrogen present as ammonia (1.20%), we have 0.39%, of which 0.12% was found by the nitrometer to consist of nitrogen in the form of nitric acid. The disposition of the nitrogen after neutral hydrolysis was therefore:—

As nitrous oxide and nitrogen	10.24%
As hydrocyanic acid	0.43
As ammonia	1.20
As nitrate	0.12
Otherwise bound and in solution	0.27
	12.26

We were thus not successful in accounting for the whole of the nitrogen. Nearly 12% of the 13% is, however, accounted for by the nitrous oxide and nitrogen and the hydrocyanic acid and ammonia.

The total solids in the solution amounted in one case to 15% and in another to 16% of the weight of the guncotton hydrolysed. The purified residue examined in the polariscope showed a *laevo*-rotation and was found to contain besides ammonia, tartaric acid, formic acid, and hydroxypyruvic acid. It exerted a strong reducing action on Fehling's solution, but the figures obtained, expressed as dextrose, varied so much with different preparations that no conclusions could be drawn from them.

Further work on this reaction carried out in an autoclave fitted for temperature and pressure readings showed that the action commenced at a temperature between 185° and 190° C., and was not explosive but gradual. Unfortunately, the notes, including diagrams of the curves and further analyses had to be left behind by one of the authors on leaving Russia in 1917, and there does not seem to be any prospect of their being recovered.

Some attempts were made to effect the decomposition without the use of pressure, e.g., by raising the boiling point of water by the addition of neutral salts, with the object of obtaining larger quantities of the decomposition products for their more complete examination. These were unsuccessful, but we have recently ascertained that guncotton readily dissolves in hot glycerin, the hydrolysis apparently taking a similar course to that shown with water under pressure. Incidentally it may be mentioned that cordite when heated with glycerin also evolves gases and goes into solution.

Note on the action of caustic soda on guncotton.

It is well known that the nitrocelluloses dissolve more or less readily in caustic alkali. The more highly nitrated products dissolve even in the cold, while if the nitration has not proceeded far an elevated temperature is required. It has been found that even if the nitration has not proceeded far enough to affect the inflammability of the cotton material, the latter may nevertheless be rendered soluble by prolonged boiling in caustic alkali, and advantage was taken of this by one of the authors in 1897 to prepare a groundwork of partially nitrated cotton for lace manufacture (Eng. Pat. Appl., 14,642 of 1897), which would be destroyed in the process of bleaching. The nitration was effected by immersing the cotton fabric for ten minutes in a mixture of 100 pts. nitric acid of sp. gr. 1.415 and 40 pts. concentrated sulphuric acid, care being taken not to allow the temperature to rise above 20° C. A similar result was obtained by denitrating a more

highly nitrated fabric by means of ammonium sulphide to a point at which, while retaining its solubility in caustic alkalis, it has lost its inflammable character.

It is further known that when the nitrocelluloses dissolve in caustic alkalies a complete breakdown of the cellulose molecule ensues, and many researches have been carried out on this question. Probably the most elaborate of these is that of Berl and Smith (J., 1908, 537; and Z. ges. Schiess- u. Sprengstoffwesen), who succeeded in identifying a large number of organic compounds in the products of cold and of hot alkaline hydrolysis.

When a nitrocellulose is dissolved in caustic soda* it is found that the solution contains both nitrate and nitrite, and there are on record several attempts to estimate quantitatively the relative proportions of these two acids. The most recent investigation in this direction is that of Carlson (Ber., 1907, 1192), who gives results obtained on a number of organic nitrates. Of these only one, viz., methyl nitrate, was found to be hydrolysed with caustic alkali without any accompanying reduction of the nitric to nitrous acid. Carlson dissolved a known weight of the nitrocellulose in alcohol and ether and added a solution of caustic soda, the whole being allowed to stand for several hours. The solvent was then distilled off in a vacuum, the residue introduced into an evacuated flask, and after the addition of potassium iodide and hydrochloric acid the liberated iodine titrated with thiosulphate. He found in this way that 82% of the total nitrogen was given off as nitrite.

Carlson's pyroxylin (with 12.5% N), being soluble in alcohol and ether, did not represent the most highly nitrated cellulose, and it seemed of interest to ascertain how such a product would behave when dissolved directly in warm caustic soda.

The mode of procedure was to dissolve a known weight of guncotton in caustic soda on the water-bath and after cooling the solution and making up to a known volume to titrate with this solution into a definite volume of standardised aniline hydrobromide in presence of an excess of hydrobromic acid. It was previously ascertained that the method gave correct results by titrating with a solution of known strength and containing caustic soda into an acid solution of aniline hydrobromide. By adding a known amount of potassium nitrite to the caustic soda solution of a known weight of guncotton it was shown that the organic substances had no effect on the accuracy of the result, the whole of the additional nitrite being exactly accounted for in the titration result. The total amount of nitrogen which had passed into solution as nitrite and nitrate in the hydrolysis was estimated as ammonia by distillation with caustic soda and aluminium borings and was found to be very nearly identical with that found in the guncotton by means of the nitrometer.

The guncotton employed for the experiments was prepared in the same way as that used for the neutral hydrolysis and contained 13.04% N.

The principal results obtained are given in the following table:—

Guncotton used	Nitrogen by nitrometer %	Mean %	Nitrogen as nitrite %	Mean %	Percentage of total nitrogen reduced to nitrite
Sample No. 1	(1) 18.05 (2) 13.08	13.07	(1) 8.49 (2) 8.5	8.49	65%
Sample No. 2	(1) 12.98 (2) 13.05	13.02	(1) 8.32 (2) 8.5	8.4	64.6%

*In spite of the absolute dissimilarity of the two substances it is remarkable that guncotton when being dissolved in hot caustic soda should evolve a smell similar to that produced when wool is being dissolved to the same reagent.

The amounts of nitrogen in solution estimated as ammonia were for sample No. 1 13.2% and for No. 2 13.1%.

It is thus seen that under the conditions of the experiment about 65% of the nitric acid present is reduced in order to provide the oxygen for the organic oxidation products which result from the hydrolysis. This figure is about 17% lower than that found by Carlson, but this may be accounted for by the fact that we used a more highly nitrated cellulose and hydrolysed under different conditions.

It will be evident that the extent to which the nitrogen is reduced in the alkaline hydrolysis is nothing like as great as when the hydrolysis is conducted in water.

College of Technology, Manchester.

DISCUSSION.

Mr. L. G. RADCLIFFE was particularly interested in the fact that hydrocyanic acid was produced by the action of the alkali upon nitrocellulose. He had had a somewhat similar experience during the course of certain experiments in connection with nitrated oils when he had endeavoured to remove the nitro or nitrate group in nitrated ricinoleic acid. The nitrogen was not entirely removed by boiling with alcohol-potash, but some ammonia was evolved.

Mr. D. M. PAUL asked if the laboratory-prepared guncotton samples were actually neutral. It was difficult to remove traces of acid in the laboratory. The purity and stability of guncotton in manufacture depended upon the removal of acid from the fibre.

Mr. J. GRANT asked if the authors had noticed during the hydrolysis of guncotton by water at such high temperatures as 195° C., that as caramelisation had occurred whether furfuroids or any saturated hydrocarbons had been formed. Apparently the whole of the hydrogen had not been accounted for in the organic acids stated to be present.

Capt. BOSTOCK said that every care had been taken in the preparation of the guncotton, and it was washed thoroughly and repeatedly in warm water. In reply to Mr. Grant, he said that when the experiments had been made at the definite temperature at which they had worked caramelisation did not occur. There was no noticeable formation of methane.

Prof. KNECHT said that Mr. Radcliffe's observation regarding the formation of ammonia from nitrated ricinoleic acid was of great interest. It might be explained upon the basis of Henry's results.

Meeting held at Armstrong College on April 21, 1920.

PROF. P. PHILLIPS BEDSON IN THE CHAIR.

THE SETTING OF CALCIUM SULPHATE CEMENTS.

BY C. L. HADDON, M.Sc.

Calcium sulphate exists in three chemical forms, as the dihydrate $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, the hemihydrate with $\frac{1}{2}\text{H}_2\text{O}$, and the anhydrous salt. Anhydrous calcium sulphate occurs naturally as anhydrite in limestone rocks or with deposits of common salt. The hemihydrate, apart from its manufacture, is found in boiler scale. The dihydrate occurs naturally as fibrous gypsum or satinspar, and as crystalline gypsum or alabaster.

On heating gypsum to about 120° C., it loses three-fourths of its combined water, and forms the hemihydrate (plaster of Paris), which is more soluble in water than the dihydrate. If excess of plaster of Paris is shaken with water and rapidly filtered, a clear solution is obtained, but this quickly becomes turbid due to the precipitation of the dihydrate. It is to this property that plaster of Paris owes its setting powers. When mixed with water the hemihydrate dissolves and the solution becomes supersaturated with respect to the dihydrate, and this is deposited. It has been shown by Le Chatelier that the crystals deposited radiate from different centres and interlock, thus giving the final product the usual properties of a set cement. The temperature of the formation of the hemihydrate is 170° C.

On further dehydrating gypsum the anhydrous salt is formed under normal conditions between 160° and 170° C.¹ The setting properties of the anhydrous salt depend on the temperature of dehydration, but several contradictory statements exist on the subject.²

According to Desch, calcium sulphate partially loses its property of setting with water if heated to 200° C., regains it at 500° C. (at which temperature flooring cement is made), and loses it again at higher temperatures. At its best it sets much more slowly than plaster of Paris, although Roscoe and Schorlemmer state that gypsum dehydrated over phosphorus pentoxide between 60° and 70° C. sets even more rapidly than plaster of Paris.

Owing to its rapid setting, plaster of Paris is mixed with excess of water into a thick cream and then poured into the mould. The time of hardening depends on the amount of water present. The larger the percentage of water present the smaller will be the percentage by volume of cement and the further the crystals must grow before they interlock.

In one experiment two lots of 680 g. of plaster of Paris were mixed with 300 c.c. and 400 c.c. of water respectively with the following results:—

Time.	Tensile strength. (lb. per sq. in.)	
	300 c.c.	400 c.c.
15 min.	70	†
30 min.	220	50
1 hr.	300	230
2 hrs.	300	230

† Broke in machine.

680 g. of plaster theoretically requires only 126 c.c. of water.

In the course of time the excess of water evaporates, depositing the dihydrate on the exposed arms of the crystal clusters and thereby increasing the tensile strength. Thus in the second case mentioned above the strength on drying rose to 350 lb. per sq. in., while similar briquettes kept under conditions which prevented drying did not increase in strength after the first hour.

Analysis of two different kinds of anhydrous cement—fine and medium—showed about $\frac{1}{2}$ % of combined water, a trace of iron and alumina, and in the case of the medium $\frac{1}{2}$ % of calcium carbonate.

In the work described below the strength of the cements was measured by making moulds 1 sq. in. in cross section, and pulling them with the ordinary cement-testing machine till they broke. A tensile test gives more concordant results than a crushing test, is easier to carry out, and requires less material. The briquettes were made as follows: The plaster was sifted through a sieve with 2500 meshes per sq. in. to remove coarse particles and then weighed out and mixed intimately with a measured quantity of water until the paste was homogeneous. Some of the paste was then placed in a previously vaselined mould and rammed till all the air holes were pressed out by means of a

cylindrical brass rod $\frac{1}{2}$ in. in diameter and 9 in. long, which was allowed to fall about $\frac{1}{2}$ in. on to the plaster. This operation was repeated till the mould was full, when it was levelled off.

The method of filling the moulds affects the tensile strength of the material, so that for comparative results a definite method of filling must be adhered to.

When the briquettes were hard they were removed from the moulds and then broken as occasion demanded. They were weighed 6 hours after making, and also daily.

Consideration of the appended data obtained by varying the percentage of water and time of setting show that although more water is originally added than is theoretically necessary, yet it evaporates so quickly that all the cement does not become hydrated. Only about 80% of the plaster was saturated when as large an excess of water as possible was used, and even then there was a tendency for the excess of water to separate and be unequally mixed. Even in the samples kept over water for a week, to prevent premature drying, the cement was by no means fully saturated.

From table 3 it will be seen that the briquette takes a week to dry, but that most of the excess of water had dried off by the end of the second day. Comparison of Tables 1 and 4 shows the very great effect on tensile strength of the excess of water present. In view of the mode of formation of the crystals, it appears probable that as the water evaporates it deposits its dissolved gypsum on the crystalline arms, strengthening them, and hence the mechanical strength of the whole briquette is increased. After 24 hours the mass is hard, and after 6 hours the briquettes are sufficiently hard to be removed from the moulds. The maximum strength is reached in about 10 days; when the briquette is put in water it falls to about 400 lb., i.e., the same strength as when the briquette was prevented from drying.

It is well known that the time of setting of flooring cement is affected by the addition of different salts. Rohland³ considers that substances which increase the solubility of calcium sulphate also increase its rate of setting. This seems fairly easily explained, as if the solubility is increased the rate of solution will also be increased and the rate of precipitation of the dihydrate, or setting, should also be increased. Experiments made with calcium chloride confirmed this. A 5% solution of calcium chloride, according to Lunge,⁴ reduces the solubility of calcium sulphate at ordinary temperatures by one-half; table 1 shows its retarding effect on the setting of flooring plaster. Contrary to this theory there is, however, one class of substances which, as far as I can discover, in dilute solutions invariably decrease the solubility of calcium sulphate and have a great accelerating effect on the setting of the plaster.

Sullivan⁵ showed that in dilute solutions ammonium sulphate decreased the solubility of calcium sulphate, although concentrated solutions had the opposite effect. Cameron and Bell⁶ showed that the injurious effect on the solubility of calcium sulphate increases with rising atomic weights in the series hydrogen, magnesium, ammonium, sodium, and potassium, while Bell and Taber⁷ showed that dilute solutions of copper sulphate decrease its solubility, though more concentrated solutions increase it to the same degree as its solubility in water.

To examine the comparative effect of various sulphates tests have been made with the sulphates of hydrogen, Cu, Fe^{II}, ammonium, Fe^{III}, Al, 5% solutions being mixed with the plaster instead of water. The first effect was to increase rapidly the

rate of setting; in the case of copper sulphate the cement was stronger after 6 hours than with water alone after 24 hours. This very rapid setting also had a secondary effect in that the water was absorbed before it could evaporate, the result being that at least 90% of the cement was fully hydrated, and thus the damping of the cement while it is setting is unnecessary.

The results obtained with medium cement are shown in table 2, from which it will be seen that after the first day the strength decreases, and then increases again. This peculiarity was noticed in every case with 5% solutions, and will be referred to later.

Briquettes made in hot weather with equal parts by volume of plaster and sawdust set when a 5% solution was used, but owing to the rapid evaporation they would not set when water alone was used, i.e., tensile strength failed to reach 50 lb. per sq. in., and they could be crushed with the fingers.

The addition of a soluble sulphate results in the formation of much smaller and finer crystals. As the vapour pressure of a solution is less than that of water the water will take longer to evaporate, and thus the briquette will be longer in drying. This was found to be the case (see table 3); it was also seen that the maximum tensile strength is not attained until the briquette is dry.

Further tests were made to ascertain the effect of varying the strength of the ferrous sulphate

solution. With a 3% solution the strength remained constant for three days and then increased. With a 1% solution the increase was continuous, and with a 10% solution the setting was accelerated more, but the strength did not increase, as in the other case, within seven days of making.

Cohn⁸ has shown that calcium sulphate is more soluble in ammonium acetate solutions than in ammonium sulphate. The effect of 5% solutions of these two salts was examined. The cement used was coarser than on the previous occasions and contained more iron oxide, but the results (table 5) showed conclusively that ammonium acetate retarded the setting, and ammonium sulphate accelerated it, contrary to Rohland's theory.

It might be thought that an ammonium acetate solution would accelerate the setting, as it would react with the calcium sulphate, forming an equilibrium mixture of four salts, but it must be remembered that calcium acetate would also be formed, and this exercises a retarding effect.

It is difficult to explain satisfactorily the depressing effect of other sulphates in dilute solution on the solubility of calcium sulphate. Davis has brought forward some evidence to show that when plaster of Paris sets orthorhombic crystals are first formed, and subsequently change into normal monoclinic crystals, the customary form for the dihydrate. Obviously, when a change is taking place a fall in tensile strength must occur. Setting

⁸ J. Prakt. Chem., 1887, H. 43-56.

⁹ J., 1907, 727.

and change would go on side by side with neat cement, the drop effect due to change being masked by the increase in tensile strength, due to setting; while with the more rapidly setting sulphate solutions, one more or less follows the other, and the effect is noticed. This seemed a simple explanation, but if it is noticeable with sulphate solutions it should be much more noticeable with plaster of Paris and water. I was, however, unable to find any trace of it on the second or third day. On the other hand, it may be due to the excess of water present, as table 4 appears to show. It is obvious that after the initial set one is dealing with a fairly concentrated added sulphate solution, and that solution may have some deleterious effect, but a full explanation does not seem possible at this juncture.

The time for the complete hydration of calcium sulphate mixed with water is at least a week (see table 3). Table 1, on the other hand, shows that it had mostly set by then and that it will be impossible to ensure 100% saturation unless the particles are infinitely small. The first maximum for sulphate solutions shows that about 24 hours is necessary with a 5% solution.

In conclusion:—

(1) Plaster of Paris forms a weak cement because of the large excess of water, and hence the smaller percentage of cement. The crystals are also much finer grained than with any other calcium sulphate cement.

(2) Neat calcium sulphate cement must be kept damp to ensure fairly complete hydration. This is not necessary if a sulphate solution is added; a 3–5% solution mixed to a thick paste gives the best cement.

(3) Contrary to Rohland's theory, sulphates exert a marked accelerating effect.

(4) With 5% or stronger sulphate solutions a peculiar drop occurs in the tensile strength after the first day, and the cement subsequently becomes stronger on drying.

DISCUSSION.

Mr. S. H. COLLINS referred to the theory that the tensile strength of wood was decreased by the addition of water or oil, which liquid acted as a lubricant to the fibres. That theory could not be ignored when studying plaster.

Mr. G. WEYMAN said that during the purification of oxide of iron in gas works the presence of water vapour prevented the hard setting to a large extent.

Mr. HADDON, in reply, agreed with Mr. Collins that the explanation of lubrication might apply equally well to cements. The increase in tensile strength on drying was very probably due to some such effect. The question of the dehydration of gypsum was very important. Gypsum cements should never be used where they were exposed to heat; that appeared to explain Mr. Weyman's difficulty with iron oxide, in which case the steam heat dehydrated the plaster. The colloidal theory of the setting of calcium sulphate was not supported by experimental evidence so far as he was aware.

Meeting held at Armstrong College on Wednesday, March 3, 1920.

PROFESSOR P. PHILLIPS BEDSON IN THE CHAIR.

A COMPARATIVE METHOD OF DETERMINING THE HEAT OF CARBONISATION OF COAL.

BY GEOFFREY WEYMAN, M.Sc., A.I.C.

During the carbonisation of coal in continuous vertical retorts the coal is continually abstracting heat from the heating surfaces as it passes down

the retort. The rate at which any specified coal can be passed through and effectively carbonised depends on the rate at which heat can be supplied to the heating surfaces, and this depends in its turn on the thickness and conductivity of the material between the heating flues and the retorts, and the temperature difference between each side of this material. The rate at which the coal can be efficiently carbonised in a particular setting depends on the temperature maintained in the heating flues, since it may be assumed that a certain minimum temperature must be obtained on the inside of the retort. The limit of temperature maintained in the heating flue is fixed by the refractory properties of the brickwork.

If we consider the temperature of the heating flue as raised to a maximum and the rate of coal passing through the retort as also regulated to a maximum consistent with the production of a well-burnt off coke, we can see the effect of altering the type of coal passing through, keeping these conditions constant. When a change is made to a more highly bituminous coal of high coking value, the temperature of the heating flue falls, the coke withdrawn begins to show uncarbonised matter, and ultimately raw coal appears. The make of gas per hour also falls off. Either more heat must be supplied or the rate of carbonisation must be reduced. With a coal more of the steam-coal type—a coal less "fat"—the heat supplied to the setting must be reduced or the rate of coal supply increased.

The rate at which coal can be passed through with efficient coking and with the same supply of heat to the heating flues varies up to 30% according to the type of coal used. The make of gas obtained from a setting varies in a similar manner from 25% to 30%. This variation is naturally of very great importance, particularly in the case of continuous vertical retort plants which are capable of easy adjustment. With horizontal retort plants the effect is to a large extent masked by the fixed times of charging.*

The power of continuous vertical retorts to distinguish coals is merely the result of a more skilful and scientific method of carbonisation, and the fact that losses of heat in dealing with different types of coal has hardly been noticed in working with horizontal retorts is very much to the disadvantage of the latter. A coal which can be carbonised quicker in vertical retorts can also be carbonised quicker in horizontal retorts, and by selecting such as give good results in vertical retorts and using them in horizontals the charging of the latter may be made at shorter intervals, and hence the capacity of the plant per day increased.

For the reasons given above an attempt was made to determine this variation experimentally. An endeavour was made to enclose in a calorimeter a known quantity of heat, and then to introduce into it a weighed quantity of coal. The coal subjected to this amount of heat should be carbonised to an extent depending on how far the enclosed heat was sufficient to decompose it. It would be reasonable to suppose that if the heat were not sufficient the evolution of gas would be small and would cease rapidly, as the absorption of heat by the coal reduced the temperature below the minimum necessary. The evolution of gas was taken as the criterion of the rate of carbonisation, and it was thought possible that the heat required to raise the coal to distillation point might be differentiated from that required to carry on the distillation. How far these ideas were achieved will be seen in the results.

The apparatus used was roughly as follows:—A fireclay furnace 8 in. external diam. was enclosed

* Constam & Schl pfer observe that in a small scale horizontal coal-testing plant, the rate of distillation varies with the type of coal. (See Gas J., 1906, 98, 460.)

in a metal vessel from which it was separated at the sides and bottom by asbestos packing. Inside the furnace was placed a crucible 3 in. x 4 in. high in which a known weight (usually 1 kg.) of copper was melted by the blowpipe operating through an aperture in the vessels and lining. When the copper was molten the blowpipe was withdrawn and the hole plugged with asbestos and the lid packed with asbestos placed on. As soon as the first crystals of copper began to form, or when the temperature of the copper fell to some pre-determined temperature as read by a pyrometer, a thin steel tube containing a weighed quantity of the powdered coal was thrust into the middle of the copper. The tube communicated with a washing bottle and meter, which was read every minute until the evolution of gas had practically ceased. The tube was then removed and the pellet of coke examined.

The following are some of the results obtained on powdered air-dried samples containing 8–10% of ash:—

Readings in hundredths of a cubic foot of gas evolved during each minute.

Total, ft. per ton	5081	5740	7021	9245	10,620	3963	4166	2438	2083	6096	9143	9956	13,110	11,670

The first three results marked (A), using the same coal, show that increasing the amount of copper increased the extent to which the carbonisation is carried. In the fourth result marked (A) the effect is more marked when the weight of coal is reduced. In the two tests marked (B) on another coal the effect is similar. (B2) is another sample of the same coal (B) taken some months later from another consignment. Although the results (B2) are nearly double those (B), both are of the same order and at the lower limit of the scale. (A2) is a similar sample of the coal (A). The difference in the results from different samples of the same coal is such as might reasonably be expected, and is not of an essential nature. In (C) again we see that the weight of coal is an essential factor.

In a general way the method gives consistent results and a true indication of the comparative amounts of heat required to carbonise the coals.

Taking a weight of 10 g. of coal and 1000 g. of copper as a standard conditions, the types of coal used may be arranged in order of the total amount of gas evolved:—(B) 4000, (C) 6000, (A) 10,000, (E) 10,000, (J) 12,000, (F) 13,000. Arranged according to the amount of gas evolved during the first two minutes the following is the order:—(B) 1.4, (A) 2.3, (C) 2.9, (E) 4.8, (F) 6.1, (J) 10.0.

Thus (B) takes by far the most heat, and probably needs raising to a high temperature before giving up any appreciable quantity of its gas. (C) also requires much heat, but starts sooner than (A), which requires a less total quantity. (E) requires still less heat and evolves its gas more readily, while (F) is superior in each respect. (J) is however astonishing in its readiness to give off its gas. These results agree very well with the experience of the coals in large scale practice.

It must be admitted that the method appears somewhat crude. One of the chief troubles was to get the tube free from adherent copper for further use. This trouble was to some extent obviated by coating the tube with black lead.

Why different coals should give such large differences in the rate of carbonisation is not clear. It has been our experience that when efficiently carbonised the yield of gas and tar per ton of any of these coals is very nearly the same, but the gas is lower in carbon content, and the tar is thinner and more paraffinoid in the case of those coals which carbonise more readily. The yield of coke is distinctly greater in the latter case.

On the whole it appears to me that the primary decomposition of coal is exothermic, but that secondary reactions, particularly further decomposition of the tar, will turn the process into a decidedly endothermic one. In the method outlined above secondary reactions will be included. It is probably the further decomposition of the tar

first formed which causes the greater part of the differences observed. (See also Constam and Kolbe, Gas J., 1908, 103, 384; Hollings and Cobb, Gas J., 1914, 126, 917; Lessing, J., 1912, 465.)

Communication.

THE ANALYSIS AND COMPOSITION OF CRESYLIC ACID.

BY J. J. FOX, D.SC., F.I.C., AND M. F. BARKER, D.SC., A.I.C.

The present communication deals with the methods whereby the proportions of the three cresols in cresylic acid may be determined in a comparatively ready manner. Certain statements as to the composition of cresylic acid are on record, but they mostly refer to the proportion of one or two constituents which can be recovered in a more or less pure state and do not indicate the composition of the original mixture. A fairly full account of these results may be found in Lunge's "Coal Tar and Ammonia" (Part 1, 1916, p. 291 etc.).

To determine the composition of cresylic acid it is necessary to be able to estimate the phenol, if present, and at least one of the cresols with a fair degree of accuracy. Phenol can be determined as already described by us (J., 1917, 842) and *m*-cresol by Raschig's process (Z. angew. Chem., 1900, 14, 759).*

* Dawson & Mountford's process (J.Chem.Soc., 1918, 113, 923) may also be used for phenol, and the method suggested for *p*-cresol on page 943 is available as a check on this constituent.

For our present purpose we have restricted the term "cresylic acid" to tar acids distilling up to 210° C. and then refractionated up to 203° or 204° C. with a good column of the Raschig type. Most of the phenol is presumed to have been removed in the works, leaving only cresols in the fraction referred to. This fraction of the tar acids usually contains less than 10% of phenol. When more is present the determination of the phenol is liable to an error of 2–3%, but we are not aware of any process which gives closer results with commercial material. In any case, for the purpose of analysis, the proportion of phenol can always be brought below 10% by adding a suitable amount of *m*-cresol.

Raschig's nitration process for *m*-cresol has been criticised from time to time, and in order to test its validity we prepared pure *m*-cresol in three different ways. As the results are of great importance for this work, we shall describe them in some detail.

(1) *Raschig's sulphonation method of preparation* (Ger. Pat. 114,975 of 1900).—For this process crude *m*-cresol was sulphonated and the sulphonic acid hydrolysed as previously described (J., 1918, 265 T etc.). The degree of purification effected as determined by Raschig's nitration process is shown by the following results: *m*-Cresol as purchased, assay 46.5%; after first sulphonation, 94.8%; after second sulphonation, 99.0%. The last product was fractionated and the middle fraction acetylated. The acetate was then fractionated and the middle fraction hydrolysed. The resulting cresol was separated into three portions by fractional distillation, the middle fraction again being the only one used. This assayed 99.0% and froze at +3.0° C. As Mr. J. M. Weiss, of the Barrett Manufacturing Co., of New York, had some time ago informed us that he had succeeded by repeated sulphonation in raising the freezing point of *m*-cresol to about +10° C., we sulphonated a large quantity of *m*-cresol seven times and obtained a product freezing at +9.6° C. This material, as well as all the products after the third sulphonation, assayed between 99.0 and 100.0% by the Raschig nitration method. The sulphonation process is applicable for the purification of *m*-cresol because the sulphonic acids derived from phenol, *o*- and *p*-cresols are not decomposed at a temperature which suffices for the decomposition of *m*-cresolsulphonic acid. In fact, it is possible to separate as little as 1% of *m*-cresol contained in *p*-cresol by the Raschig sulphonation process. The method is, however, conceivably open to the criticism that some substance is carried through the whole process, and on that account two other methods were employed.

(2) Thymol was treated with phosphoric anhydride as described by Tiemann and Schotten (Ber., 1878, 11, 769) and the product purified by distillation from the other products of the reaction. The yield of *m*-cresol was only 15% of the theoretical quantity; it froze at +2.8° C., and assayed 99.0%, but may, of course, contain a small proportion of some impurity not removed by fractional distillation.

(3) *m*-Toluidine was converted into *m*-cresol by means of nitrous acid. Kahlbaum's *m*-toluidine was used, and, in addition, some was prepared from benzaldehyde, according to the method of Widman and Ehrlich (Ber., 1880, 13, 676; 1882, 15, 2010). The *m*-cresol so obtained was impure, but after removing the tar and higher boiling phenols a product was isolated freezing at +10.4° C. and assaying 99.0% by the nitration process. This *m*-cresol possessed the highest freezing point of all the samples prepared by us.

The *m*-cresol from (2) and (3) darkens more rapidly than that from (1) when exposed to light. All three preparations assay from 99.0 to 100%, and the "crude" trinitro-*m*-cresol obtained during the

assay has m.p. 105°–107° C. We have confirmed Raschig's statement that 17.4 g. of trinitro-*m*-cresol is obtained from 10 g. of pure *m*-cresol. This value also applies to the assay of mixtures of widely different composition, as shown by the following results:—

Composition of mixture.	<i>m</i> -Cresol determined.
<i>m</i> -Cresol 89.8%, phenol 10.2%	89.1%
<i>m</i> -Cresol 89.6%, <i>p</i> -cresol 10.4%	89.6%
<i>m</i> -Cresol 90.0%, <i>p</i> -cresol 10.0%	87.5%
<i>m</i> -Cresol 79.5%, <i>o</i> -cresol 20.5%	78.4%
<i>m</i> -Cresol 53.0%, <i>o</i> -cresol 47.0%	51.5%

As mixtures of the three cresols with less than 10% of phenol all gave equally close results for *m*-cresol, we conclude that Raschig's nitration method is sufficiently accurate for technical purposes.

We have found that, in applying Raschig's process the best results are obtained by the following slightly modified procedure: 10 g. of the cresylic acid is placed in a 1200 c.c. flask with 15 c.c. of 98% sulphuric acid and heated on the water bath until the liquid is viscous when cooled to the room temperature. The liquid is spread in a thin layer over the bottom of the flask by quickly rotating it and then 100 c.c. of nitric acid (sp. gr. 1.4) is poured on to this thin layer. The flask is replaced on the water-bath at once. In a few seconds a violent reaction occurs which is allowed to proceed unchecked. From this point Raschig's procedure is strictly followed. The product obtained should melt between 102° and 107° C. after drying and should be free from tar. When conducted as described the method can be relied upon for all mixtures, the important point of the whole process being the initial sulphonation. It is also an advantage, when the proportion of *m*-cresol is found to be less than 25%, to repeat the assay after adding sufficient pure *m*-cresol to the original cresylic acid to raise the proportion of the *m*-cresol to about 50%.

In addition to Raschig's method for the estimation of *m*-cresol we have worked out another process which is capable of giving accurate results. This method depends on bromination in a dry solvent, such as carbon tetrachloride, and is based on the fact that in such a solution and with excess of dry bromine, *m*-cresol yields a tribromo-derivative, whilst phenol, *o*-cresol, and *p*-cresol yield only di-bromo-derivatives. About 1 g. of the dried cresylic acid is weighed into a tared flask fitted with a small ground-in tap funnel and an outlet having a glass stopcock. Excess of a carbon tetrachloride solution of bromine containing 200 g. of bromine per litre is slowly dropped into the flask by means of the funnel and the mixture allowed to stand for several hours at ordinary temperature. It is then warmed very gently on the water-bath until most of the bromine has been expelled, care being taken that the temperature does not exceed 50° C. The apparatus is connected to a pump and the solvent very slowly distilled off at about 30 cm. pressure, the temperature of the water bath being kept below 50° C. When the flask is dry the tap funnel and the side tube are removed and the increase in weight due to the bromination is determined. To ensure complete bromination the process may be repeated, but in general this is unnecessary. The temperature of heating should be kept as low as possible, because the bromo-derivatives are appreciably volatile above 70° C. The results found with the pure substances are as follows, the figures referring to the weight of bromo-derivative obtained from 1 g. of substance taken.

It is clear that if *m*-cresol contained, say 2% of phenol, *o*- or *p*-cresol, it would be easily detected by this method. All three specimens of *m*-cresol prepared as described gave results which showed them

to be of at least 99.5% purity, and the melting-

		Calculated.	Found.	M p. of bromo-derivative.	
				Crude.	Purified.
Phenol	..	2.681	2.700	36°	36°-40°
<i>o</i> -Cresol	..	2.463	2.449	56°	56°-57°
<i>m</i> -Cresol	..	3.194	3.189	80.5°	81°-82°
<i>p</i> -Cresol	..	2.463	2.481	47.5°	48°-49°

point of the crude tribromo-*m*-cresol was in no case less than 80.5° C. This method is lengthy, but affords a valuable check on the Raschig nitration method. It is also available for mixtures of the three cresols, using the equation,

$$\% \text{ } m\text{-cresol} = (100 W - 246.3) \div 0.731,$$

where *W* is the weight of bromo-derivative obtained from 1 g. of the mixed cresols. The following are a few of the results obtained with synthetic mixtures:—

Weight of bromo-derivative (per gram).	<i>m</i> -Cresol (found).	<i>m</i> -Cresol (actual).
3.027	77.0%	78.0%
2.701	32.6%	33.3%
2.566	14.1%	14.4%

We have also worked out a third method of determining *m*-cresol which consists of a modification of that originally suggested by Ditz and Cedivoda (Z. angew. Chem., 1899, 13, 873; 1900, 14, 1050). The original process has been subjected to adverse criticism by Russig and Fortmann (Z. angew. Chem., 1901, 15, 160), but as it is very rapid we thought it worth while to investigate it carefully with a view to removing the difficulties connected with the process. Ditz and Cedivoda state that under the conditions given by them *o*- and *p*-cresol use up exactly 2 mols. and *m*-cresol 3 mols. of bromine per mol. of cresol. The process is carried out by shaking for exactly one minute an aqueous solution of cresol with bromine obtained from acidified potassium bromide and bromate, and liberating iodine from potassium iodide with the excess of the bromine. We find that on shaking for the prescribed time, *m*-cresol absorbs exactly 3 mols. of bromine, but *o*- and *p*-cresols absorb rather more than 2 mols. of bromine. Our results, after numerous assays, are as follows, the figures referring to the weight of bromine absorbed per mol. wt. of substance:—

	Phenol.	<i>o</i> -Cresol.	<i>m</i> -Cresol.	<i>p</i> -Cresol.
Found ..	482.8	333.3	478.6	331.5
Calculated ..	480.0	320.0	480.0	320.0

In the method as laid down by Ditz and Cedivoda there is considerable difficulty in obtaining an end-point in the titration of the liberated iodine with *p*-cresol, and to a less extent with *m*-cresol, because the iodine is apparently adsorbed by the bromo-derivative and is only slowly given up to the aqueous liquid. A false end-point is thus obtained, which recurs persistently. As much as 7 to 10 c.c. of *N*/10 thiosulphate must be sometimes added over a period of about 30 min. after the titration is apparently finished. We have therefore substantially altered the process and adopted the following procedure. About 1 g. of the cresol is weighed into a 200 c.c. graduated flask; 5 c.c. of 2*N* sodium hydroxide solution is added and the liquid diluted to the mark with distilled water. 10 c.c. of this solution is placed in a well-stoppered flask of about 300 c.c. capacity. To this is added an excess

(100 c.c.) of a mixture of equal parts of *N*/20 potassium bromide and *N*/100 potassium bromate, followed by 10 c.c. of hydrochloric acid (sp. gr. 1.08). The flask is closed and sealed by running a little water round the stopper and shaken for exactly one minute. The stopper is then removed only far enough to allow the addition of 20 c.c. of a 10% potassium iodide solution, the latter being introduced in such a manner that throughout the addition the liquid always forms a seal round the stopper. These precautions prevent loss of bromine vapour, and thus remove a serious source of error in the assay. The flask is placed aside for one hour and the liberated iodine is titrated. Towards the end of the titration 10 c.c. of carbon tetrachloride is introduced. This has been found desirable in order to produce a sharp end-point, and is due to the solution of the mixture of bromocresol and iodine in the carbon tetrachloride. As a result of numerous tests we find that *m*-cresol takes up 480 g. of bromine per 108 g. of cresol, this being nearly the theoretical quantity. On the other hand, *o*- and *p*-cresols require 333 and 332 g. of bromine respectively per 108 g. of cresol. Calculating to bromine absorbed per gram, 1 g. of *m*-cresol is equivalent to 4.444 g. of bromine, and 1 g. of *o*- and *p*-cresol are respectively equivalent to 3.080 g. of bromine very nearly. If *X* = % *m*-cresol and *Br* = bromine actually absorbed, the percentage of cresol is given by

$$X = (100 \text{ Br} - 308) \div 1.364.$$

The results obtained with synthetic mixtures containing *m*-cresol up to 50% are within 2% of the actual amounts present. With larger percentages of *m*-cresol (80% or so) the results are from 3 to 4% too low, and in such cases it is better to add *o*-cresol to the original cresylic acid in order to bring the percentage of *m*-cresol down to about 50%. With the modifications given above this bromine method is very rapid and sufficiently accurate for general work. The bromine factors for *o*- and *p*-cresols are empirical, but it was found that they were valid over a large range of synthetic mixtures, whilst the theoretical factors gave serious discrepancies, except with cresylic acids in which *m*-cresol is present to the extent of 80% or more.

We are now in a position to utilise these three methods for determining *m*-cresol in cresylic acid, and by ascertaining the sp. gr. accurately at 15.5°/15.5° C. we have all the data necessary for determining the *o*-cresol and the *p*-cresol actually present. The only assumption made is that the sp. gr. of a mixture of the three cresols is additive to the fourth decimal place, and this will be found to be true, or very nearly so, in all cases. Thus sp. gr. 1.0433 was found instead of 1.0434 calculated, for a mixture of cresols containing 5.4% phenol and 54.0% *m*-cresol, and 1.0434 was found for 1.0434 calculated for cresols containing no phenol and 31.5% *m*-cresol. The values for the sp. gr. of the constituents used by us for this purpose are 1.0774 for phenol, 1.0516 for *o*-cresol, 1.0388 for *m*-cresol and *p*-cresol; and the formula connecting specific gravity and composition is

$$G = [1.0774 \times P + 1.0388 \times M + 1.0516 \times O + 1.0388 (100 - P - M - O)] \div 100.$$

In this equation, *G* is the observed specific gravity at 15.5°/15.5° C.; *P*, *M*, *O*, and (100 - *P* - *M* - *O*) are the percentages of phenol, *m*-cresol, *o*-cresol, *p*-cresol respectively.

This expression simplifies to 0.0386 *P* + 0.0128 *O* = 100 (*G* - 1.0388), in which *O*, the proportion of *o*-cresol, is the only unknown quantity. If no phenol is present, the equation is simply 0.0128 *O* = 100 (*G* - 1.0388).

The last equation applies to all mixtures of the three cresols, such as "tri-cresol" and commercial *m*-cresol. The following table gives a few results

that we have obtained by the utilisation of the aforementioned equations:—

	1	2	3	4	5	6	7	8
Phenol	9.7 (10.0)	4.6 (5.1)	1.1	11.0	20.0	16.6	nil	3.4
<i>o</i> -Cresol	54.6 (55.4)	35.2 (33.4)	nil	11.3	32.1	31.2	37.8	28.0
<i>m</i> -Cresol	15.1 (17.1)	30.1 (30.8)	72.0	44.3	11.7	20.2	16.7	33.5
<i>p</i> -Cresol	20.6 (17.5)	30.1 (30.7)	24.4	18.5	29.4	17.3	45.5	35.1
Xylenols	—	—	—	14.9	6.8	14.7	nil	nil

(1) and (2) are synthetic mixtures, the actual composition being given in brackets. (3) was purchased as "80% meta-cresol," (4) is a "mixed" cresylic acid consisting of a mixture of about two hundred samples of cresylic acid from which the phenol had been stated to have been removed by the manufacturers, (5) and (6) are samples of cresylic acid containing comparatively large amounts of phenol. (7) is a sample of "tri-cresol" and (8) a colourless cresol free from xylenols. The deficiency in (3) is due to water. The "xylenols" consisted of the fraction which, on re-distillation with a Raschig column, did not distil below 205° C. In general the xylenols so separated had sp. gr. 1.0326 at 15.5°/15.5° C. The cresylic acids from which (4) was derived were collected about four years ago, and were all supposed to contain less than 10% phenol. So far as could be traced they included no tar acids of blast furnace origin. We have found that the *o*-cresol result may be as much as 3% low when much phenol is present, and within 2% of the actual quantity in the absence of phenol. This, of course, tends to make the *p*-cresol result too high, since it is taken by difference.

We have applied the method to ascertain the composition of distillates from cresylic acid fractionated out up to 195° C., some of the results being the following:—

	Phenol.	<i>o</i> -Cresol.	<i>m</i> -Cresol.	<i>p</i> -Cresol.	Sp. gr., 15.5° 15.5° C.
1	24.8	39.1	17.9	18.2	1.0534
2	—	64.1	16.5	19.4	1.0470
3	—	68.0	15.1	16.9	1.0475
4	—	72.1	14.1	13.8	1.0480

This table refers to distillates obtained by adding ortho-cresol to cresylic acid and distilling the mixture to 195° C. preparatory to determining phenol (J., 1917, 842). From these and other results we have found that this fraction of cresylic acid nearly always contains from 65% to 75% of *o*-cresol and, if phenol is present also, the total proportion of phenol and *o*-cresol in the distillate is also from 65% to 75%.

Approximate results for the *o*- and *p*-cresols can be obtained by observing the refractive index of the mixture of cresols at 50° C. by means of the Abbe refractometer. The refractive indices used by us for this purpose are $n_D = 1.5309$ for *o*-cresol, 1.5266 for *m*-cresol, and 1.5260 for *p*-cresol. The formula connecting n_D and the percentage is given by $O = (100 n_D - 0.0006 M - 152.6) \div 0.0049$, in which $O = \%$ *o*-cresol, $M = \%$ *m*-cresol, and n_D is the observed refractive index at 50° C. The latter can be determined at any two convenient temperatures and the necessary correction for 50° C. applied. Thus 36.3% *o*-cresol, 31.5% *m*-cresol and 32.2% *p*-cresol gave a reading of 1.5277, the calculated reading being 1.5279. Taken in conjunction with the third method for assaying *m*-cresol previously described, this procedure is very useful when only approximate results are required, owing to its rapidity. It cannot, however, be employed with advantage unless a large proportion of the mixture consists of *o*-cresol, because the refractive indices of *m*-cresol and *p*-cresol are too close to each other. This condition

can always be secured by adding 40% of *o*-cresol to the original cresylic acid.

We take this opportunity of commenting upon the criticism of our curves by Dawson and Mountford made in the footnote to their paper (J. Chem. Soc., 1918, 113, 923. See also our paper, J., 1918, 265 r). The statement that our *m*-cresol contains 15% of *p*-cresol is without foundation, as it assayed 99.0% by Raschig's process, 100.3% by the first bromination process, and only slightly under 100% by the second bromination process, but it froze at a lower temperature than the *m*-cresol employed by Dawson and Mountford. With *m*-cresol freezing at +10.4° C. we have obtained curves higher than our original curves for *m*-cresol and the other phenols. We also found a eutectic point on our *m*-cresol and *p*-cresol curve with 12% concentration of *p*-cresol and at +0.15° C., which we failed to observe with *m*-cresol of lower freezing point. Our original curves must be corrected for *m*-cresol of freezing point +10.4° C., but the results for the lower freezing *m*-cresol still hold good. We have also repeated our observations for the pairs, phenol-*p*-cresol and *o*-cresol-*p*-cresol, attention being paid more particularly to the eutectic points shown in our previous paper. These observations confirm our previous results. As our method of determining "freezing" points, or to be more precise, depression of freezing point, is a cryoscopic one, it cannot be expected to give the same results as those obtained by Dawson and Mountford, who determine the temperature at which complete solution occurs. It is well known (e.g., the determination of the "titre" of fatty acid mixtures) that the melting point or temperature of disappearance of all solid matter in a mixture of closely related substances is higher than that of the freezing point or "titre." As a matter of fact, pure cresol mixtures are even more complicated than the curves indicate, for at least one other set of curves can be obtained in the following manner. The mixture of the cresols is cooled, and the lowering of the freezing point is determined in the usual way (a); the mixture is then melted in the same apparatus and the temperature adjusted till it is just above that of (a). A crystal of the main constituent is then introduced, and the mixture well stirred, when the temperature will be found to rise to a second maximum (b) and then fall to the temperature of the external cooling bath. The solids separating in (a) and (b) are different; in (a) the liquid is filled with a heavy deposit or shower of crystals, whilst in (b) only a few crystals separate. The phenomenon recalls that described by Miers and Isaac (Proc. Royal Soc., A, 1907, 79, 322) for mixtures of betol and salol. More than 4° C. difference between the two curves may sometimes be observed, but we have determined only a few points on this second curve and have not followed it further.

It should be noted that we have confined our investigations to such cresylic acid as can be obtained commercially, and have not made any special examination of cresylic acid from different kinds of tar. We have, however, as far as possible excluded tar acids of blast furnace origin.

We desire to express our indebtedness to Sir J. J. Dobbie, F.R.S., for permission to publish the results in this paper.

THE VISCOSITY OF SOLUTIONS OF NITRO-CELLULOSE IN ETHER ALCOHOL.

BY WILLIAM HOWIESON GIBSON AND ROBERT McCALL.

In the manufacture of cordite R.D.B., which was extensively employed as a propellant during the war, the gelatinisation of the nitrocellulose is effected by means of a mixed solvent of ether and

alcohol. Owing to difficulties which were experienced in the early stages of manufacture, an investigation was made into the viscosity relationships of cellulose and nitrocellulose solutions and standardised conditions were arrived at.

The present paper deals with the observations made on the viscosity of nitrocellulose in ether-alcohol and the influences affecting the viscosity of such solutions. It has been demonstrated that when suitable conditions are chosen the viscosity of an ether-alcohol solution is characteristic of the nitrocellulose used, and is therefore a useful criterion in the examination of nitrocellulose. All the viscosity determinations referred to in this paper were made by means of the Falling Sphere viscosimeter, as described by Gibson and Jacobs (*Chem. Soc. Trans.*, 1920, 117, 473). This method is very suitable for use with viscous solutions such as are obtained with fairly strong concentrations of nitrocellulose.*

Initially solutions of nitrocellulose in ether-alcohol for viscosity determinations were obtained by dissolving 4 g. of dry nitrocellulose in 100 c.c. of the mixed solvent ether and alcohol, solution being facilitated by mechanical shaking. At the Research Department, Woolwich, the ratio of ether to alcohol used in the mixed solvent was 3:2 by volume, and in factories the ratio used was 3:3.75. In both cases the specific gravity of the solvent constituents was the same, being, ether 0.72 and alcohol 0.817 (92% by wt., approx.) at 15°/15° C.

Usually it was found that solutions of nitrocellulose in the factory solvent gave viscosity values about 70% of those obtained in the Woolwich solvent. This, however, was not invariably the case, for sometimes the factory method yielded values much higher than the Woolwich method, while in other cases the values were almost identical by the two methods. The following are a few typical examples:—

TABLE I.

Source of nitrocellulose.	Viscosity, Woolwich.	Viscosity, Factory.
Queensferry	3.33	3.61
Gretna blend 1076 ..	87.32	75.2
do. 1094 ..	79.6	94.1

Such variation in the values for viscosity evidently called for some explanation, as did also the peculiar results obtained in the determination of the viscosity of several nitrocelluloses of high nitrogen content. Thus it was observed that the viscosity of some of these did not show a constant value after the solution had assumed the temperature of the bath. The time of fall of the ball increased, and in some cases the solutions eventually became so viscous that the ball would not fall through them. The solution at this stage had set to a stiff jelly.

Other solutions which had shown a rise had a gelatinous appearance. Further, it was always those solutions which had a jelly-like appearance that gave this rise in viscosity on standing. In some cases the solutions were already quite gelatinous when removed from the shaker, and no viscosity determinations were possible.

To arrive at a better understanding of these facts, a study was made of the effects of varying the proportion of ether to alcohol in the solvent.

Viscosity determinations with varying proportions of ether-alcohol.

The nitrocotton used was a soluble nitrocellulose with a nitrogen content of 12.2%, as used for R.D.B. manufacture at Waltham Abbey. The nitrocotton was dried in a steam oven for 1½ hrs. at 95° C. and cooled for 15 mins. in a vacuum desiccator before weighing, an operation which was performed within a period of two minutes on account of the hygroscopicity of the nitrocellulose.

The weighed nitrocotton was placed in a stout bottle of about 250 c.c. capacity and the alcohol added; the whole was well shaken and allowed to stand for about 15 mins., and then the ether was added. The bottle, with its contents, was then vigorously shaken for a few minutes and placed in a shaking machine overnight. The viscosity was determined by the falling sphere method at 20° C., about an hour being allowed for the solution to attain equilibrium. The following table gives the times of fall of the sphere with these solutions:—

TABLE II.

Viscosity of 4 g. nitrocellulose (12.2% N) in 100 c.c. of ether-alcohol.

Ratio ether : alcohol. (vol.).	Viscosity, (time in secs.).
80 : 20	160.7
75 : 25	59.6
70 : 30	39.9
60 : 40	28.8
50 : 50	23.1
45 : 55	26.1
40 : 60	30.5
30 : 70	90.4

These results are shown on Graph I. (B). The curve is a striking one. It will be seen that a minimum viscosity value is obtained when the ratio of ether to alcohol is approximately 55:45 by volume or about 1:1:1 by weight. As the ratio of ether to alcohol is increased or decreased the viscosity rises until it reaches a maximum at 80:20 on the one hand and 30:70 on the other. With ratios outside these values the nitrocotton was not dissolved.

The range of mixtures of ether-alcohol, 100 c.c. of which would dissolve 4 g. of this nitrocotton, is thus between 80:20 and 30:70. The optimum solvent for the nitrocotton was that containing the ether and alcohol in the proportion 55:45 by volume, gel formation taking place to a greater or less extent according as the solvent used was removed from, or approached that composition. The solutions obtained with the 80:20 and the 30:70 solvents had a distinctly jellied appearance. The time of fall of the ball increased in both cases on standing, and eventually the solution became so viscous that the ball would not fall. The values given are those obtained from the first ball dropped after the solution shaken over-night had stood for 1 hour at 20° C.

It is important to note that the rise in viscosity occurred at both ends of the curve, excluding the possibility that the rise was due to loss of ether during the experiment. The effect of a slight loss of ether might account for a rise at the alcohol-rich end of the curve, but at the ether-rich end would produce a fall.

In one case, with a solvent rich in alcohol, the time of fall of the ball changed in the manner shown in Table III.

The initial period was taken as 20 mins. after the solution had been transferred to the viscosimeter tube after having been shaken over-night for 14 hrs.

* In the cases in which the absolute viscosity has not been calculated, the time of fall in seconds of a $\frac{1}{16}$ -inch ball through 15 cm. has been given; this is almost proportional to the viscosity, as the density changes are small.

TABLE III.
Alteration of viscosity with time.

Period. Mins.	Viscosity, time of fall (secs.).
15	102.5

In another case, with solvent rich in ether, the time of fall of the ball increased from an initial value of 557 secs. to a value of 619 secs. in a period of 8 hrs. at 20° C. A determination of the amount of solvent lost in that time (by weighing) gave a loss of only 0.02 g., showing that the concentration had not appreciably altered. These experimental facts are evidence of actual gelation having taken place in the solution.

GRAPH 1.

Solutions of nitrocellulose. Waltham Abbey R.D.B. in ether—alcohol. The values W and F are those obtained from the Woolwich and factory solvent respectively.

The experiments just described indicated that the proportion of ether to alcohol played an important part in the determination of the viscosity, and also that with excess of either constituent variable results are obtained. Both of these subjects were therefore further investigated.

Effect of concentration of nitrocellulose.

In order to ascertain to what extent the viscosity ether-alcohol curve would be influenced by changes in concentration, the viscosity curves of 3%, 5%, and 6% solutions were determined, with the results given in Table IV. The procedure in

making up the solutions was the same as in the case of the 4% solutions.

These results are represented in Graph I., curves A, C, and D.

The curves obtained were all similar in form to that of the 4% solutions. The chief point of interest lies in the fact that the minimum viscosity value was always obtained when the ratio of ether to alcohol was approximately 55:45, showing that concentration has little or no influence on the minimum point.

Further, as the concentration increased the range of ether-alcohol mixtures which would dissolve the nitrocellulose diminished, and formation of the gel took place more abundantly and readily.

TABLE IV.

Ratio. Ether:alcohol (vol.).	Viscosity (time in seconds).		
	3 g.*	5 g.*	6 g.*

30 : 70	13.8	—	—

* Weight of nitrocellulose per 100 c.c. of ether-alcohol.

Table V. gives the viscosity values for each concentration and optimum solvent. The concentration by weight was calculated in each case.

TABLE V.

Relation between concentration of nitrocellulose and optimum solvent.

Concentration of nitrocellulose solutions.		Viscosity (secs.).	Log T.
g. per 100 c.c.	g. per 100 g.		
3	3.93	9	0.9542
4	5.22	24	1.3802
5	6.55	76	1.8808
6	7.86	250	2.3979

On plotting the logarithm of the time against the concentration by weight the curve obtained is a straight line.

Arrhenius (Biochem. J., Aug., 1917) obtained a very similar relationship from Baker's measurements of the viscosities of nitrocellulose in acetone solution (J. Chem. Soc., 1913, 1653). Arrhenius' formula, which has some theoretical foundation, may be expressed: $\log \eta = \theta C - \log \eta_0$, where η and η_0 are the viscosities of solution and solvent respectively and C is the concentration of the nitrocellulose; θ is a number which proved to be approximately constant for a narrow range of concentrations.

Influence of the nitrogen content of the nitrocellulose on the ether-alcohol viscosity curve

Having established that the minimum point of the viscosity ether-alcohol ratio curve was not affected by changes in concentration of the nitrocellulose, it was necessary to determine to what extent it might be influenced by a change in the nitrogen content of the nitrocellulose. Determinations were according made on nitrocelluloses containing 12.55% and 11.8% nitrogen respectively with the following results. Solutions containing

4 g. of nitrocellulose in 100 c.c. of solvent were used in each case:—

TABLE VI.
Nitrocellulose of 12.55% nitrogen content.

Ratio. Ether: alcohol (vol.).	Viscosity (secs.) of nitrocellulose with	
	12.55% N.	11.8% N.
90 : 10	—	Very long.
80 : 20	Very long.	198
75 : 25	12.9	—
70 : 30	7.6	45
65 : 35	8.5	—
60 : 40	9.0	34.6
50 : 50	17.2	32.2
40 : 60	Very long.	33.2
30 : 70	—	37.6

Some of the above results are represented in Graph II.

GRAPH II.
Nitrocellulose of nitrogen content 12.55%.
4 g. N.C. per 100 c.c. E.A.

The minimum viscosity and optimum ether-alcohol ratio of the solvent for each nitrocellulose, as read from the curves, are as follows:—

TABLE VII.
Optimum solvent with varying nitrogen content of nitrocellulose.

Nitrogen content, %	Min. viscosity (secs.).	Optimum ether-alcohol ratio.	
		By vol.	By wt. (approx.)
11.8	31.8	50 : 50	0.9 : 1
12.2	23.1	53 : 47	1.0 : 1
12.55	7.6	70 : 30	2.1 : 1

It is established from these results that the optimum solvent for a nitrocellulose depends on its

nitrogen content, and that the higher the nitrogen content, the more ether the optimum solvent requires.

It will be seen that in the case of the nitrocellulose containing 12.55% N, the range of ether-alcohol mixtures which dissolve it is much smaller than that of the nitrocellulose with 12.2% N, and this range again is less than with 11.8% N. It might be expressed as a value, namely, the range of composition for the ether-alcohol mixture which will give measurable viscosity at given concentration and temperature. For one concentration it would be represented by the line XY on Graph II.

Conclusions.—With a given nitrocellulose, the viscosity of its solution in ether-alcohol is dependent upon the ratio of ether to alcohol, and reaches a minimum value at a definite ratio. On either side of this "optimum" ratio the viscosity rises with increasing steepness; it was owing to this steepness that the former Woolwich method and the "factory" method, in both of which solvents diverging considerably from the optimum compositions were used, gave such irregular results.

Within the limits studied the optimum ratio of ether to alcohol does not depend upon the concentration of nitrocellulose in solution; on the other hand it is a characteristic property of the particular nitrocellulose, and its determination can be made repeatedly with concordant results. As far as can be seen at present the governing factor is the nitrogen content.

The minimum viscosity of a given sample of nitrocellulose reached in the solvent of optimum composition is again a definite and characteristic property, and repetitions of its measurement can be made with very satisfactory agreement. The value of this minimum viscosity is affected greatly by the origin and treatment of the nitrocellulose, and so the determination of this minimum value affords a guide to uniformity in manufacture.

ADDENDUM.

The influence of nitroglycerin on the viscosity of solutions of nitrocellulose in ether-alcohol.

It seemed possible that the presence of nitroglycerin in cordite might modify the action of ether-alcohol solvents in such a way as to alter the relationships which have been described above, and consequently experiments were carried out to test this question.

The viscosity values have in most cases been expressed in absolute units; the times of fall of a $\frac{1}{16}$ -in. steel ball through 15 cm. of the solutions in a 2 cm. tube have also been quoted.

The nitrocellulose used was made at Waltham Abbey for cordite R.D.B., and the ether and alcohol were of the same sp. gr. as before.

The nitroglycerin was extracted from dynamite. Its density at 20° C. was 1.60. Its viscosity, as determined with the Ostwald viscosimeter, was 0.3774 C.G.S. unit at 20° C.; this value is nearly 40 times the viscosity of water, and about 1/22 that of glycerin at the same temperature.

In the first place the nitroglycerin and ether-alcohol were taken in the proportion in which they occur in the manufacture of cordite R.D.B.

Three ether-alcohol mixtures were used, namely, 70:30, 50:50, and 30:70 by volume. The composition of the solutions was therefore as follows:—

TABLE VIII.

Effect of nitroglycerin in large proportion.

Solution.	Ratio ether-alcohol (vol.).	Wt. of ether-alcohol mixture.	Wt. of nitro-glycerin.	Wt. of nitro-cotton.
1	70 : 30	g. 57.3	g. 42.7	g. 5
2	50 : 50	57.3	42.7	5
3	30 : 70	57.3	42.7	5

In the case of solution 3 the nitrocellulose was not dissolved. Solutions 1 and 2 were too viscous for any measurement to be made, although qualitatively it was obvious that solution 1 was more viscous than 2. Both solutions were very much more viscous than 5% solutions of nitrocotton in ether-alcohol alone.

The following were the values obtained with 5% solutions by weight of the nitrocellulose in ether-alcohol.

TABLE IX.

Viscosity of the nitrocellulose for nitroglycerin experiments.

Ratio ether-alcohol (vol.).	Time of fall (secs.)	Density.	Viscosity (absolute).
70 : 30	23.8	0.78	12.59
60 : 40	19.2	0.79	10.14
55 : 45	20.6	0.80	10.86
50 : 50	21.4	0.80	11.29
40 : 60	36.3	0.81	14.11
30 : 70	78.2	0.82	41.44

The curve obtained on plotting the above results is similar in form to those in fig. 1, and has a minimum point when the ratio of ether-alcohol is 57.5:42.5.

The effect of replacing part of the ether-alcohol in 5% solutions of nitrocellulose by varying amounts of nitroglycerin was examined. In preparing the solutions the nitroglycerin was added to the ether, which was then poured on to the alcohol-wet nitrocotton. Otherwise the procedure was the same as in the case of nitrocellulose.

The following were the values obtained, together with values for solutions in which solvent was substituted to the extent of 10, 12.5, and 20% of nitroglycerin.

TABLE X.

Effect on nitroglycerin.

	Ratio of ether-alcohol (vol.).	Time of fall (secs.).	Density.	Viscosity.
Nitro-glycerin, 5.33 g., ether-alcohol, 94.67 g.	70 : 30	39.4	0.80	20.78
	60 : 40	30.4	0.81	16.02
	55 : 45	30.6	0.82	16.09
	50 : 50	34.3	0.82	18.04
Nitro-glycerin, 10 g., ether-alcohol, 90 g.	40 : 60	58.0	0.83	30.46
	70 : 30	42.1	0.82	22.14
	60 : 40	32.8	0.83	17.23
	55 : 45	34.1	0.84	17.88
Nitro-glycerin, 12.5 g., ether-alcohol, 87.5 g.	50 : 50	39.9	0.84	20.92
	40 : 60	72.0	0.85	37.70
	65 : 35	52.0	0.84	27.79
	60 : 40	49.4	0.85	25.86
Nitro-glycerin, 15 g., et.-alc., 85 g.	55 : 45	51.4	0.85	26.92
	50 : 50	55.8	0.86	29.22
	60 : 40	66.8	0.86	34.93
	55 : 45	68.4	0.86	35.77
Nitro-glycerin, 20 g., et.-alc., 80 g.	50 : 50	83.8	0.87	43.64
	70 : 30	47.0	0.87	24.53
	60 : 40	181	0.88	83.92
	55 : 45	153	0.88	79.77
	50 : 50	166.6	0.89	86.72

The viscosity-ether-alcohol curves are normal. The minimum viscosity occurred when the ratio of ether to alcohol was 57.5:42.5, as in the case of 5%

solutions of nitrocotton alone. The curves, however, lie at a higher level, and the range of solubility is diminished.

In the case of the results with 20% of nitroglycerin the time of fall of the ball was greater after standing in every case. The times chosen are those of the first fall of the ball after the solution had stood for 2 hours at 20° C.

The chief point of interest lies in the fact that that ratio of ether to alcohol which gives the minimum was not altered by increasing the amount of nitroglycerin. As the amount of substituted nitroglycerin was increased the curves ascended to a higher level and the range of solubility was diminished. The effect was reminiscent of, but greater than, that produced by increasing the proportion of nitrocellulose present in ether-alcohol solution.

A further experiment was carried out in which varying quantities of nitroglycerin were added to 5% solutions (by weight) of the same nitrocellulose in ether-alcohol. The ratio of ether to alcohol was 57.5:42.5, this being the optimum solvent for that nitrocellulose. As in the previous experiment, the additions of nitroglycerin were made to the ether before it was added to the alcohol-wet nitrocotton.

Table XI. shows the results obtained.

TABLE XI.

Solutions of 5 g. nitrocotton in 100 g. ether-alcohol used.

Nitro-glycerin added.	Time of fall (secs.).	Density.	Viscosity.
g.			
0	23.2	0.788	12.26
2.5	23.3	0.802	12.29
5.0	23.6	0.808	12.42
7.5	23.2	0.816	12.20
10.0	24.0	0.829	12.60
12.5	24.9	0.839	13.05
15.0	25.5	0.844	13.37
20.0	25.8	0.865	13.49

After an addition of 10 g. of nitroglycerin a slight rise takes place.

Conclusions.—The optimum composition of an ether-alcohol solvent for a nitrocellulose is not affected by the addition of nitroglycerin.

Substitution by nitroglycerin of a proportion of the ether-alcohol solvent in a solution of nitrocellulose results in a solution of viscosity approximately equal to that of a similar solution in which the equivalent volume of solvent is absent. This holds only for small substitutions.

Nitroglycerin does not act as a solvent when added to solutions of nitrocellulose in ether-alcohol, the viscosity of the solution tending to be increased rather than decreased by such addition.

This work was carried out at the Research Dept., Royal Arsenal, Woolwich, and is published by permission of the Director of Artillery, War Office, to whom our thanks are due. We also desire to express our thanks to Lieut.-Col. R. A. Craig, C.M.G., the Superintendent of Research, and to Sir Robert Robertson, K.B.E., F.R.S., the Superintending Chemist, for the interest they have taken in this work.

MR. L. P. WILSON IN THE CHAIR.

CATALYTIC ACTION IN THE OXIDATION OF CELLULOSE.

BY L. P. WILSON, F.C.C.I., F.I.C.

In the manufacture of artificial cellulose fibres from cellulose, the most commonly employed method is the viscose process, in which cellulose sodium xanthate is produced and dissolved in dilute alkali to form a solution. This solution is projected through fine apertures into a coagulating medium, and so is formed into filaments.

The first stage in the production of a solution, whether the starting material be wood or cotton is the formation of alkali cellulose by immersion in a solution of caustic soda of over 15% strength; this causes a partial gelatinisation of the fibres and the formation of a definite chemical compound which, after a process of oxidation and subsequent reaction with carbon bisulphide, forms sodium cellulose xanthate, a brownish plastic solid, which is soluble in water, forming a liquid of high viscosity.

Whether or not the cellulose xanthate will form a solution which can be used for the production of threads depends largely on the exact amount of oxidising action to which the alkali cellulose is submitted; this is in any case very small, but it causes an alteration in the molecular arrangement of the cellulose, and determines whether the xanthate when mixed with water is a stiff gel or a liquid less viscous than glycerin; the chemical difference between these two conditions cannot be stated, but the physical differences are most marked.

This oxidation has been generally effected by exposure to the atmosphere, and at the ordinary temperature—say 20° C.—the process may take four days. If oxygen is introduced by other means—such as by treatment with peroxides or hypochlorite—this time may be reduced in proportion to the activity of the oxidising agent employed. For instance, 1% of sodium peroxide added to the caustic soda solution used to produce the alkali cellulose results in a sufficient oxidation taking place during a steeping period of about 5 hrs.

Whichever method of oxidation is employed—exposing to air after the formation of alkali cellulose, or oxidising while still in the caustic soda solution—the process can be greatly accelerated by the use of suitable catalysts. These catalysts are generally oxides or hydroxides of metals which exist in two states of oxidation, e.g., iron, nickel, cobalt, cerium, vanadium, manganese. The catalyst is applied either by first impregnating the cellulose with a salt of the metal, or by suspending the hydrated oxide in a fine state of division in the caustic soda solution; as an example, sheets of wood pulp may be soaked in a solution of nickel sulphate containing 0.33% nickel oxide and then pressed to such a weight that they contain 0.25% of nickel oxide and dried. The sheets of pulp are then steeped in caustic soda of the usual strength, containing in addition about 0.8% of sodium peroxide. Immersion for $\frac{1}{2}$ hr. under these circumstances will produce the required change in the cellulose, which would have taken four or five hours without the catalyst to accelerate the oxidation. The same sort of effect is obtained by using iron solutions of suitable strength and exposing the alkali cellulose to atmospheric oxidation. In this case 0.1% of FeO will accelerate the process, so that it takes about one-fourth of the normal time. The amount of change which takes place, and which is indicated by the viscosity of the xanthate, is proportional to the

amount of oxygen absorbed, and does not depend on the state of the oxygen, i.e., whether it be free atmospheric oxygen or combined, for example, either as hypochlorite or peroxide. As far as is known, these variations only affect the rate of reaction, which is, of course, greatly dependent on the presence, nature, and quantity of catalyst, if any, employed.

The effect of the catalyst in a heterogeneous system of this type depends, to a large extent, on its distribution and its fineness of division, so that it is difficult to give accurate relative values for different metals. The following figures, however, indicate the comparative effects of a number of metals—applied under as nearly as possible equal conditions—in modifying the molecular state of the cellulose:—Without catalyst, 100; nickel, 9; vanadium, 22; cobalt, 28; iron, 33; cerium, 42; manganese, 60; chromium, 77; lead, 200; manganese and lead, 45. It will be observed from these figures that lead has a negative value, giving a figure greater than the blank. When, however, it is used in conjunction with manganese, the effect of the two together is greater than that of manganese alone. Apparently, therefore, lead, although not an oxidising catalyst when used by itself, acts as a catalytic accelerator in conjunction with manganese.

DISCUSSION.

Dr. E. B. MAXTED observed that in the hydrogenation of oils it was easier to measure the absorption of hydrogen than to ascertain the iodine value of the oil. With the rate of the shaker constant the curves were quite smooth. The method might be applied to the oxidation of cellulose.

Dr. D. F. TWISS enquired concerning the evidence as to the relationship between viscosity and oxidation; with rubber there was no such simple connection. On what experiments was the assumption as to the proportionality between the extent of chemical action and that of the physical change in cellulose actually based?

Mr. WILSON pointed out that the difference in viscosity was the measure, more or less direct, of the molecular change of the cellulose, and that change had been correlated with the actual absorption of oxygen, and the corresponding viscosities had been obtained in a parallel set of experiments on a larger scale. The figures, while not the actual direct measure of the activity, were fair in a comparative sense, and placed the metals approximately in the right order. The fineness of division of the metallic compounds had considerable effect. The method employed was similar to that suggested by Dr. Maxted. It was not necessary in the case of cellulose to have shaking, because the material was very open and exposed a large surface to the action of the oxygen.

MR. JULIAN L. BAKER IN THE CHAIR.

THE FERTILISING VALUE OF SEWAGE SLUDGES.

BY WINIFRED E. BRENCHELEY AND E. HANNAFORD RICHARDS.

(Rothamsted Experiment Station.)

The sewage sludges produced by the usual methods of tank treatment have never been highly valued as manure. As a rule farmers within easy reach of the works have been willing to take the sludge when they could get it without payment,

but in many places the local authorities have had to pay for its disposal by burial, burning, or other means. In a few cases where the sludge is prepared specially for sale as a fertiliser and is put on the market in a convenient form, no difficulty is experienced in disposing of it at a price which at any rate pays the cost of manufacture.

That the farmers are right in their low estimate of the manurial value of sewage sludge in the forms generally available is shown by the results of many field trials designed to test the fertilising constituents of sludge in comparison with equivalent amounts of artificial manures. The most complete series of trials was made under the auspices of the Royal Commission on Sewage Disposal about twelve years ago.*

Seven types of sludges produced by various methods of settlement or chemical precipitation showed practically no manurial value when applied to mangolds, turnips, and hay crops on farms in England and Wales. Further, pot culture experiments with wheat carried out by Dr. Voelcker at the Woburn Station of the Royal Agricultural Society gave a maximum increase over the unmanured pot of only 15%. Some of the sludges gave negative results. The samples giving the best yields contained large amounts of lime added to facilitate pressing into cake. Dr. Voelcker reported that none of the sludges was worth 10s. per ton to the farmer.

Although there is no doubt that the nitrogen, by far the most valuable constituent in sewage sludge, is mostly present in a form very difficult of digestion by the soil organisms, it may be argued that the field trials of the kind just mentioned did not give the sewage sludges a fair chance. It is unreasonable to compare the effect of nitrogen in a substance like sewage sludge, to be obtained for the asking, with equal amounts of nitrogen in the form of ammonium sulphate, or sodium nitrate costing £21 per ton. A much better comparison can be made with farmyard manure if both sludge and dung are applied at the same rate of dry matter per acre. Thus a dressing of 10 tons of farmyard manure (20% dry matter) should be compared with 4 tons of sludge (50% dry matter). Tested in this way over a complete rotation the sewage sludge would probably show a small increase over the unmanured plots, but far below that given by the dung. Giving every possible chance to the sludge it must be admitted that it is of little value to the farmer.

Within the last ten years at least two new methods of sewage treatment have been introduced, viz., slate beds and activated sludge. Both these processes yield sludges of definite manurial value, as is clearly shown by the experiments described below.

As regards activated sludge the process as a practical method of sewage purification is hardly yet out of the experimental stage, but the claims made for its fertilising value appear to be thoroughly justified, and the present results merely confirm tests made elsewhere.†

In the case of the sludge from slate beds, although this has been recognised as superior to the ordinary tank sludges,‡ we are not aware that any quantitative tests of its manurial value have been published. This material is decidedly inferior to activated sludge as a fertiliser, but, since it is produced without the cost of air compression or agitation, and can be easily dried, it is by no means to be despised. On the other hand, it must be remembered that the slate bed effluent requires further treatment on filters in order to reach a degree

of purity comparable with that attained by the activated sludge process in one operation.

It has long been known that the suspended matter washed out from percolating filters—so-called humus—is an excellent manure. It resembles activated sludge in many ways and forms a useful "starter" for the more rapid production of this material from the suspended matter in raw sewage. One feature common to all three types of solid residue, viz., slate-bed sludge, filter "humus," and activated sludge, is that they are produced under aerobic conditions of increasing thoroughness in the order given. On the other hand, the old tank sludges tested by the Sewage Commission were all essentially anaerobic sludges, varying only in the time they had been allowed to remain on the tank bottoms from which air is practically excluded. It seems probable that the access of air combined with the presence of suitable surfaces for the deposition of colloids—another feature common to the slate bed, percolating filter, and activated sludge methods—are the factors which produce the marked increase in manurial value of these sludges compared with the older tank deposits.

Chemical analyses of sludges.

The samples of sludge used in these experiments were (1) activated sludge (Withington) and (2) slate bed sludge (Harpenden). The activated sludge was supplied by Dr. Arden from the continuous flow plant at Withington, Manchester. It was fairly well divided and in good condition for applying to the soil. The Harpenden sample came from a heap of air-dried sludge taken from the settling tanks which intercept the suspended solids washed out from the slate beds, the effluent passing on to the percolating filters. An analysis of pressed cake from precipitation tanks at Derking is added for comparison.

Sludge.	Activated. %	Slate bed%,	Precipita- tion, %.
Moisture	7.26 ..	55.65 ..	37.67 ..
Organic matter	76.72 ..	20.76 ..	24.81 ..
Inorganic matter (grit)	16.02 ..	23.59 ..	37.52 ..
Calculated on the sludges dried at 100°C.			
Nitrogen	7.09 ..	2.83 ..	0.89 ..
Phosphoric acid	3.82 ..	0.34 ..	0.66 ..
Potash	1.12 ..	0.08 ..	0.07 ..

The nitrogen is by far the most valuable constituent in the sludges. Six of the usual tank sludges tested by the Sewage Commission for manurial value contained an average of 1.22% N. The slate bed and activated sludges are from 2 to 6 times as rich.

To estimate the probable manurial effect of the nitrogen, its quality must be considered as well as its total amount. In ordinary tank sludges the bulk of the nitrogen is of an insoluble type, quite useless to plants and very difficult of digestion by the soil organisms, whose function it is to convert the insoluble residues into soluble plant food. The best way to determine the quality as distinct from the quantity of nitrogen is to see how much of it is converted into nitrate when the manure is allowed to decompose in the soil.

Nitrification experiments were made with both sludges in comparison with dried blood, the manures being added at the rate of 60 parts of nitrogen to 1,000,000 of soil.

Nitrogen as nitrates: Pts. per million of dry soil.

	At start	After 32 days	After 106 days	After 200 days
Soil only	7.3 ..	10.7 ..	17.5 ..	16.8 ..
Soil+slate-bed sludge	7.3 ..	18.0 ..	33.1 ..	33.2 ..
Soil+activated sludge	7.3 ..	32.3 ..	56.0 ..	60.9 ..
Soil+dried blood	7.3 ..	34.0 ..	77.6 ..	75.2 ..

Both the sewage sludges thus contained nitrogen in a form capable of nitrification, but there is a great difference in the proportion of the total

(1) Royal Commission on Sewage Disposal. 5th Report. Appendix VIII. (1908).

(3) Mumford, J. Bd. Agric., 1916, 23 (2).

nitrogen available in the two samples. In 15 weeks 26% of the nitrogen in Harpenden slate-bed sludge is converted into nitrate. In the same time 66% of the Withington activated sludge has been nitrified, and the action continues slowly up to 200 days. The dried blood was taken as a check on the nitrifying power of the particular soil used. It behaved normally as the whole of its nitrogen was nitrified in 15 weeks.

Evidently both kinds of sludge have manurial value. The pot culture experiments described below show that the crop increases induced by the sludges are roughly proportional to the availability of the contained nitrogen as found in the nitrification experiments.

Pot experiments were carried out in triplicate in glazed earthenware pots. The soil chosen for use was poor, in order that the response to the manures applied should be sharply marked, and, as it was rather heavy and inclined to clog, an admixture of 10% of sand was made. Each pot contained 35.4 lb. of soil, to which was added in every case 16 g. superphosphate, 8 g. potassium sulphate, and 160 g. calcium carbonate. Nitrogenous manures were then added as follows:—

Pots 37-39.—No nitrogenous manures added. (Control.)

Pots 40-42.—16 g. sodium nitrate.

Pots 43-45.—41.6 g. activated sludge, containing the same amount of nitrogen as 16 g. sodium nitrate.

Pots 46-48.—219.6 g. activated sludge, containing six times the amount of nitrogen in 16 g. sodium nitrate.

Pots 49-51.—116 g. slate-bed sludge, containing half the amount of nitrogen in 16 g. sodium nitrate.

Pots 52-54.—232 g. slate-bed sludge, containing the same amount of nitrogen as 16 g. sodium nitrate.

(Owing to the low nitrogen content of Harpenden sludge it was not possible to apply it in the proportion of 6:1 of nitrogen added as sodium nitrate.)

First crop.

Barley was sown on April 24, 1918, with seeds graded between 0.04 and 0.05 g. Ten seeds were sown per pot, but as soon as the seedlings were about 2 inches high they were thinned out, leaving the five strongest in each case. Observations were made throughout the growing period, and at the close of the experiment (August 15) the plants were cut, the ears separated from the straw, and the green weights of both recorded. The crop was then placed in a drying-room at about 90°, and, when thoroughly dry, the weights were again taken.

Growth noted.

37-39. *Control.* The plants grew well from the first, the colour of the leaves being a yellowish-green. After two months' growth they began to look unhappy as if they were starving, for the lower leaves were dying and the tips of the upper leaves were shrivelling. This phase passed in about a week, though the colour remained very pale, and very soon after this the ears began to emerge from their sheaths, earlier than in any of the other pots, all of which had received nitrogenous manure. At the time of cutting the plants were very tall and erect.

40-42. *Sodium nitrate.* Within a month from sowing these plants were stronger and darker than the controls, and before long they began to tiller strongly. The growth became very strong, the leaves were particularly broad and dark green, but the plants were succulent and rather flabby, giving the impression that they would lodge easily. As time went on they became markedly shorter than the controls and the ears were much later in emerging from their sheaths, as the nitrogenous

Heavy dressings

Fig. 3.

manuring tends to lengthen the period of growth and to delay maturity.

43-48. *Activated sludge.* The plants receiving an equivalent dressing of nitrogen (pots 43-45) resembled the sodium nitrate plants very closely from the beginning to the end of the experiment—so closely that it would have been difficult to draw a distinction. Those with a six-times dressing of nitrogen were also very similar, but at times during growth they gave the impression of being heavier than either those with sodium nitrate or a single dressing of sludge, an impression that was borne out by the weights after cutting.

49-54. *Slate-bed sludge.* The plants all through were in striking contrast to those grown with activated sludge. The type of growth resembled that of the controls (37-39), being upright, with few tillers and pale yellowish-green leaves, maturing much earlier than the plants with sodium nitrate or activated sludge. The Harpenden sludge plants certainly looked better than the controls, and at the time of harvesting those with the full dressing of sludge (pots 52-54) were a little shorter and darker than those with the half-dressing.

still growing vigorously, and it is certain that some considerable amount of extra dry matter would have entered into the grain if it had been possible to carry the plants on longer. The unmanured plants and the slate-bed sludge plants seemed to have reached much the same stage of development, so that while the sludge did not affect the rate of maturing or the type of growth, it caused a very considerable increase in crop, amounting to 22% of the fresh weight and 31% of the dry weight, an appreciable difference outside the limits of experimental error. From this point of view, therefore, the slate-bed sludge proved to be quite a useful source of nitrogen, although unit for unit the increase was considerably less than with sodium nitrate or activated sludge. The half dressing of sludge (pots 49-51) gave plants that were very similar to those with the full dressing, except that the proportion of dry matter was somewhat lower in both straw and ears.

Second crop (for residual effect of sludge.)

The day after the barley crop had been removed the soil in the pots was thoroughly stirred up and mustard was sown. The seeds soon germinated and

A comparison of the average weights of plants grown with similar amounts of nitrogen applied as sodium nitrate, activated sludge, and slate-bed sludge respectively shows a remarkable agreement between the results of the first two treatments and a marked falling off in the case of the slate-bed sludge. With sodium nitrate and activated sludge the total green weights of the plants were practically the same, but the sludge plants had the heavier ears and the lighter straw. The dry weights show that a larger proportion of water is present when the nitrogen is applied as sodium nitrate, the percentage of dry matter in green being 47.0% with activated sludge and only 41.8% with nitrate. So far, then, as bulk of crop and percentage of dry matter are concerned, the activated sludge compares most favourably with the more usual nitrogenous dressing, giving what was practically an equal return for each unit of nitrogen applied. The use of six times the amount of sludge gave a further increase of crop, both in green and dry weight, but this increase was by no means commensurate with the extra expense of the very heavy dressing.

Slate-bed sludge, on the other hand, gives a less marked result, though the increase over the unmanured plots is considerable. The amount of dry matter in the ears, moreover, is higher than that in the sodium nitrate plots, but this may be partly due to the inevitable difference in maturity at the time of harvesting. The slate bed sludge plants were fully developed, and it is probable that the passing of food material into the grain had come to an end, so that the dry weight would not increase further. The ears of the sodium nitrate plants were not nearly so far advanced, the plants were

in a fortnight were thinned out to five per pot, no differences between the pots being then noticeable. The plants were grown for about three months before cutting.

37-39. *Control.* The plants did not make much growth but remained short and stocky and soon showed signs of starvation, while the lower leaves turned yellow and died off. These were the smallest plants all through the experiment.

40-42. *Sodium nitrate.* The plants soon ran ahead and became tall and sappy, outdistancing all others except those with a six-times dressing of activated sludge. Nevertheless, a fortnight before cutting the lowest leaves were turning yellow, and at the close many of these leaves had died off and a good many more just above were quite yellow. In spite of this all the upper leaves were very dark, and the plants were the only ones of the series that

43-48. *Activated sludge.* The plants with the single dressing resembled those with the single dressing of slate-bed sludge. They were rather better than controls, but the lower leaves had died off and growth was much behind that with sodium nitrate or the heavier dressing of activated sludge. In the latter case the plants were exceedingly strong from the beginning, and at the end they were hefty plants with very dark green leaves throughout, as even the lowest leaves showed hardly any trace of dying off. This set stood out markedly from all the rest.

49-54. *Slate-bed sludge.* As stated above, with the single dressing the plants resembled those with a single dressing of activated sludge, but the residual effect of the half-dressing was much less marked, and the plants did not look very much ahead of the controls.

Slate-bed sludge (1 equiv.) ..	52-54	42.17	5.78	13.77	79.0

From the above table and from the comparison of the growing plants it is clear that, while single dressings of slate-bed and activated sludges had a certain residual manurial value in these experiments, the actual increase of crop was not of any great significance. Sodium nitrate, however, in similar dressing left a considerable amount of available plant food, which was more than doubled with the heavy dressing of activated sludge. In the latter case the water content of the mustard plants was very high, much higher than with sodium nitrate or the lighter dressing of sludge.

From the results of the foregoing experiments it is clear that activated sludge has a very real manurial value by reason of its relatively high content of nitrogen in a readily available form. The practical difficulty of drying the sludge containing 98% of water as it comes from the settling tanks has yet to be overcome, but if an economic drying process can be found activated sewage sludge promises to become a valuable manure for the farmer and market-gardener.

There are comparatively few sewage works of any size where slate beds are in use. However, it may be worth noting that sludge from these beds has a definite manurial value and deserves the attention of farmers and gardeners wherever it is available.

DISCUSSION.

Dr. S. RIDEAL said that the most remarkable feature in the results given was the phosphorus and potash content of the Withington activated sludge. Calculated on the dry matter it contained no less than 1.12% of potash, whereas the other sludges referred to contained only 0.03%. How could the presence of this high percentage of potash be accounted for? The activated sludge also contained 3% of phosphoric acid, whilst the others contained a very small quantity. These figures might account for the fact that activated sludge was a better fertiliser than the others, quite apart from its nitrogen content. On the other hand, it was known that with all these sludges the difficulty in getting the fertilising value in an available form was largely due to the presence of oils and fats in the sludge. Perhaps distillation of the sludge would be resorted to, especially when it could be got with such a low water content as 7% as had been shown in the paper. During the war he had suggested that the soluble nitrogen of sewage might be a useful source of nitrate for explosives purposes, and he had made some calculations which showed that it would be possible to recover the soluble nitrate from filter beds if they were allowed naturally to evaporate in large covered glass areas protected from the rain—in fact, by imitating the conditions that obtained in Chili, India, and elsewhere. If it were possible to convert the whole of the nitrogen in sewage into nitrate and then evaporate the water from the filtrate, this would produce a most useful stimulant and fertiliser for plant growth.

Mr. JOHN HUGHES said that sewage sludge could be completely dried by spreading it in thin layers

and protecting it from the rain; it could then easily be ground.

Mr. E. H. SAMS said that the fertilising value of the residue from the distillation of sludge was very small; it only contained 0.7% of ammonia, and the organic matter had been destroyed. The trials carried out at Rothamsted might have been supplemented by including a sewage sludge as pumped from settling tanks on to the land.

Mr. W. T. LOCKETT agreed that it might be advantageous to subject activated sludge to some process of distillation to obtain oils, ammonium sulphate, and other compounds.

Dr. H. T. CALVERT (Ministry of Health) said that sewage sludges could be divided into half a dozen or more classes. There were chemical or precipitated sludges, sludges with trade waste, sludges with a high percentage of grease, and those with little or none. A process was in successful operation at Huddersfield in which the grease was extracted from sewage sludge by means of a solvent, and the resulting sludge was then sold as a fertiliser. This involved drying by heat, thus destroying plant seeds in the sludge, and he was hopeful that the activated sludge could be subjected to a similar process. He rather looked to that solution than to distillation. A feature of the experiments described in the paper was the large amount of activated sludge used in one pot experiment; that suggested to him that we were, perhaps, not proceeding on quite the right lines in speaking of the sludge being dependent entirely on its nitrogen content for its fertilising value. The nature of the soil ought to be taken into account, and experiments should be made in altering the nature of the soil.

Mr. RICHARDS, in reply, said that the high content of potash in the Withington sludge was certainly very striking. The figures of analyses made at Rothamsted agreed very closely with those given by Dr. Ardern as typical for this sludge. Other samples had been analysed at Withington, and the results showed that the sludge there did contain a high percentage of potash. At the same time, he was at a loss to understand why it was so high compared with other sludges. On the other hand, he thought there was some possibility of an explanation being forthcoming of the high content of phosphorus. There was a sulphur cycle and a phosphorus cycle as well as a nitrogen cycle, but very little attention had been paid to the two former, and it was possible that the phosphorus, passing from the inorganic to the organic form, might contribute in the same way as nitrogen probably did, to increase the phosphorus content of the sludge. The pot culture experiments described in the paper were only a preliminary to a fairly large piece of work which had been planned out at Rothamsted under Dr. Russell's direction. They were trying not merely to find out the fertilising value of samples of activated and other sludges, but they were producing activated sludge in sufficient quantities to test it on the Rothamsted experimental farm. Laboratory experiments were also in hand from which they hoped to get information as to where the large amount of nitrogen in activated sludge came from; was it due to the fixation of atmospheric nitrogen, as had been suggested in some quarters, or was it derived from the ammonia in the sewage? With regard to the possibilities of distillation, that was largely an engineering proposition with which he was not competent to deal. The de-watering problem had not yet been solved, and it was a very serious one. In the case of the little plant at Harpenden, the works were excavated out of the solid chalk. By making a lagoon in the chalk and pumping the sludge into it under a waterproof cover he had been able to get the sludge into a spadeable condition in about a fortnight, i.e., 15% of dry matter. In that state it could be carried on a farm cart, but beyond that it did not yield its water very readily. With regard to the

residual value of the sewage sludges when applied in heavy dressings, the pot-culture experiments were not comparable with actual operations on the farm. The pots were kept in a glass-house protected from rain, and leaching did not take place. The only water was that given when it was required, so that the results were rather better than would be obtained, probably, on the farm. Generally speaking, he thought that the fertilising constituents of activated sludge which were not taken up by the first crop had a reasonable prospect of being taken up by the succeeding crops.

Nottingham Section.

Meeting held on May 19, 1920.

MR. J. WHITE IN THE CHAIR.

THE DELIQUESCENT AND DRYING OF AMMONIUM AND ALKALI NITRATES AND A THEORY OF THE ABSORPTION OF WATER VAPOUR BY MIXED SALTS.

BY E. B. R. PRIDEAUX, M.A., D.SC., F.I.C.

The application of scientific control to the processes of drying and grinding salts will require a more complete knowledge than is at present available of the vapour pressures of the various systems which can be formed by salt hydrates, solutions, etc. In the case of anhydrous salts, which alone have been considered in this paper, the tendency of the saturated solution to lose water to an atmosphere in which the pressure of water vapour is p_1 will be a function of the ratio p_1/p , p being the pressure of water vapour in equilibrium with the univariant system, salt, saturated solution, vapour at a given temperature. The application of high drying temperatures in the hope of thereby increasing p_1 so that it is unquestionably above p , while usually successful in this object and in securing rapidity of drying, may, on the other hand, be undesirable on account of the existence of transition points or possibility of decomposition and on account of the cost of maintaining these higher temperatures. For each salt there is probably an optimum temperature in determining which the equilibrium vapour pressures must be taken into account. These pressures, p_1 , as well as those p of the atmosphere, may conveniently be referred to that of saturated water vapour p_s at the same temperature, and the dehydration tendency of the salt expressed as its relative humidity, p_1/p_s , which is comparable to the relative humidity p/p_s of the atmosphere. The greater is p_1/p_s the more favourable will be the conditions for drying the salt at ordinary temperatures. If the ratio relative humidity of salt to relative humidity of air (or p_1/p) is greater than 1, drying is possible, and a suitable figure by which to express the speeds of drying would probably be the Van't Hoff maximum work expression $4.57 \tau \log p_1/p$ for 18 g. of water. Similarly, the tendency to deliquesce under atmospheric conditions is a function of the ratio p_s/p_1 .

In the determination of the vapour pressures which will just produce deliquescence in the pure nitrates and in a mixture at various temperatures the kind co-operation of Dr. R. M. Caven is gratefully acknowledged.

Experimental.—The pressures of saturated solutions were measured by two distinct methods, i.e., by the direct and the differential tensimeter. The former (the Johnston tensimeter) was similar to that used in determining the pressures of saturated ammonium nitrate above 40° C. (J., 1919, 353 r).

On the whole, this method is preferable for measurements at higher temperatures or when only a few measurements are required for each of a series of solutions. The differential tensimeter is independent of the barometric pressure and is particularly well suited for measuring small differences of pressure at lower temperatures at which a long time may be required for the attainment of equilibrium.

The Johnston tensimeters may be in one plane, although they are often bent round for convenience of use. The differential tensimeters were of the usual type. One hull contained the saturated solution and solid salt, the other, water or another saturated solution. In all measurements the solutions were maintained at the temperatures until the pressures, or pressure differences, were constant, and at least for a quarter of an hour. When the manometer liquid was mercury the readings were corrected to mercury at 0° C. by the approximate formula $h = h_0 (1 - 0.0001733t)$. When it was bromonaphthalene the heights, h , in cm. of bromonaphthalene were multiplied by the factor $10D + 13.596$, D being the previously ascertained density of bromonaphthalene at the temperature in question. The factor varies from 1.108 at 10° to 1.090 at 35° C., and the result is in mm. of mercury at 0°.

Ammonium nitrate.

31.70	—	—	—	20.8
32.00	—	—	—	21.6

In column 5 are given the pressures determined in the Johnston tensimeter with mercury. In column 2 are the differences of pressure between water and saturated ammonium nitrate in the differential tensimeter with mercury. By subtracting these from the corresponding pressures of saturated water vapour the pressures of ammonium nitrate are obtained (column 4). They are, on the whole, about 1 mm. lower than those obtained by the direct method. A formula has been calculated which reproduces the pressure of saturated ammonium nitrate up to 32° C. $\log p = 7.425 - 1869/T$.

TABLE II.

25	14.5	0.61
30	18.3	0.57
35	23.2	0.56
38	29.9	—

The vapour pressures do not rise very sharply with rise of temperature, the increase between 11° and 32° being only about 13 mm. as against 25 in the case of pure water. Consequently the increase in speed of drying resulting from rise of temperature

is not so great as in the case of less soluble salts like potassium nitrate. Deliquescence will not take place and the salt can be dried in air of a relative humidity below 0.7 at 15°, whereas at 32° the relative humidity must be below 0.6.

Potassium nitrate.—This salt has been taken as a standard of deliquescence in Marshall's "Explosives," not only for other nitrates but also for hygroscopic mixtures such as black powder. It seemed desirable to obtain its direct relation to ammonium nitrate by means of the differential tensimeter using bromonaphthalene. The differential pressures so obtained are given in Table III.

TABLE III.

Pressures of saturated potassium nitrate solutions.

32.1	12.1	20.1	32.2

The two measurements marked with asterisks are those of saturated water vapour against saturated KNO₃. Two series of results in different tensimeters give results which differ by about 0.6 mm. in the overlapping part of the curve. On adding the pressures of ammonium nitrate, there is obtained the pressure curve of saturated potassium nitrate, which lies very close below that of water at these temperatures. The relative humidities p_1/p found thus are given in column 2 and those given by Marshall in column 5.

TABLE IV.

Relative humidity of potassium nitrate in terms of saturated water vapour.

The vapour pressures of mixed salts.—Commercial salts usually contain small quantities of others, i.e., in the case of ammonium nitrate, sodium nitrate, ammonium sulphate, etc. These affect the relative humidity, and the most important in this respect will be the more soluble salts such as sodium nitrate. A theory of the mechanism of deliquescence in such a mixture has been propounded (below) and has been tested on experimental results.

The vapour pressures of mixtures of ammonium nitrate and sodium nitrate were measured against those of pure ammonium nitrate. There are two extreme solutions possible with solid ammonium nitrate in excess, (1) that containing the two salts in the same ratio as in the mixture; and (2) that saturated with both salts. Case (1) was first investigated by means of a solution made from ammonium nitrate and 2% of sodium nitrate. The vapour

pressure differences between this and pure ammonium nitrate were somewhat irregular, but the latter was higher. The difference at the highest temperature employed (42°) was only 1 cm. of bromonaphthalene or 1.1 mm. of mercury.

Case (2) gives the most important measure of the effect of other salts, according to the opinion of T. M. Lowry, who states that when the ammonium nitrate contains 2% of sodium nitrate the deliquescence is determined by the vapour pressure of the solution saturated with both salts.

TABLE V.

Differences of pressure between saturated NH₄NO₃ and NH₄NO₃+NaNO₃.

*Upwards.

†Downwards.

The vapour pressures of a solution saturated with respect to both ammonium nitrate and sodium nitrate were measured against one saturated with the former alone, in the differential tensimeter, using bromonaphthalene and a milk-glass scale reading in $\frac{1}{4}$ -mm. The readings were converted into mm. of mercury at 0° in the manner already described and are given in Table V.; also on the graph. It will be seen that the differences in pressure are considerable—from 2.55 mm. at 10° to 11.25 at 38°. At a temperature of 30° a sample of ammonium nitrate containing sodium nitrate will absorb moisture or be impossible to dry at the low relative humidity of $14.3 \div 31.6 = 45\%$, whereas in the case of pure ammonium nitrate this limiting relative humidity is $18.5 \div 33$ or 56%. This shows the added difficulty of drying an impure salt and also, if such has to be dried, that raising the temperature is not necessarily and in all cases advantageous. (See Table VI.)

TABLE VI.

Pressures and relative humidities of saturated NH₄NO₃+NaNO₃.

t°	Pressure NH ₄ NO ₃ minus NaNO ₃	Pressure NH ₄ NO ₃ + NaNO ₃	Relative humidity.

38°	5.62	21.4	0.43

Much valuable evidence on the course of deliquescence or desiccation is afforded by the experiments of Lieut.-Col. J. A. Hall, M.Sc., D.Sc., to whose kindness the author is indebted for permission to use them in the present paper. The salt investigated was sodium nitrate, which is deliquescent under ordinary atmospheric conditions corresponding to its high solubility, 87.5 at 18° (ammonium nitrate, 182 at 18°) and vapour pressure of a saturated solution, 25 mm. at 31.8°, obtained from an extrapolation of the pressure concentration isotherm given in Landolt and Börnstein's tables. The effects of the addition of varying quantities of sodium chloride to sodium nitrate are qualitatively comparable to those of the addition of sodium nitrate to ammonium nitrate.

The method of J. A. Hall briefly consists in exposing the pure or mixed salts in an enclosed space to atmospheres of constant and definite humidity from a large excess of water, or aqueous sulphuric acid, kept at constant temperatures. The samples, of approximately the same weight, surface, and depth, were exposed in weighing bottles and weighed at intervals. It was found by preliminary experiments that these variables, and likewise the fineness of grinding, had effects on the gain of water which were only of secondary magnitude compared with those of the variables under examination: pressure of water vapour and the composition of the sample. The salts were dried to constant weight at 120° — 130° C. and ground so as to pass a 40-mesh

Pressures of saturated solutions.

Middle curve NH_4NO_3 .
Lowest curve $\text{NH}_4\text{NO}_3 + \text{NaNO}_3$.

sieve but be retained by a 60-mesh sieve. The rate of absorption of water, determined by weighing at regular intervals, shows fluctuations which are due no doubt to the effect of varying convection currents on the vapour transference and of varying rates of diffusion in the solution. These fluctuations are effectively smoothed out by continuing the comparison over long periods, and thus the differences in the rate of gain per unit weight of salt and unit time for different mixtures are clearly revealed. The absorption method is admirably adapted for investigating the behaviour of pure and commercial salts exposed to varying atmospheres for long periods. It gives little or no information, however, about the "first deliquescence" of mixtures of two salts as determined above by the tensimeter method. The final deliquescence or continued deliquescence (see below) is, however, definitely determined.

Theory of deliquescence of mixtures.

A soluble salt, A, is considered, which is mixed with a few per cent. of another soluble salt, B. A fundamental assumption, justified by general experience and a few definite measurements, is that all solutions containing both salts and saturated with respect to one (in these cases A is the more

soluble) have a lower vapour pressure than that saturated with A alone. It is applicable therefore chiefly, and in its simplest form, to salts which crystallise anhydrous and which do not form double salts under the conditions. When the mixture is exposed to water vapour, this will dissolve the surface and, no doubt, in time make its way round the grains in the interior of the mass. It will attack in the first place the particles of B which are distributed over the surface of the grains and with them form the solution, saturated with respect to both A and B, which has the lowest vapour pressure, p_1 , i.e., that which is determined by tensimeter measurements with large amounts of both A and B and their solution. On the addition of more water more solution will be formed, which is still saturated with respect to A but unsaturated to B, since there is no longer sufficient B to give the required fixed ratio of B to A. Later the whole surface of each grain will be covered with a film of solution which, given uniform distribution of B in A, finally has the same ratio of B to A as that in the total mixture. The vapour pressure rises to p_2 . The relative humidity, p_2/p_1 , which is characteristic of this long deliquescence is higher than that, p_1/p_s , of the first deliquescence. If the mixture contains 1% or less of B, p_2 may be much less than p_1 , as has already been noted in the case of ammonium and sodium nitrates. What happens afterwards depends upon the magnitude of the pressure p of the atmosphere. If this lies between p_1 and p_2 , the absorption of moisture will stop before the second deliquescence is reached, the impure salt will only take up a certain amount of moisture (cf. remark quoted from J. A. Hall's paper after Table III). In the case of pure salts, of course there is no such stabilising influence; they cannot attain an equilibrium condition of partial deliquescence, but if p is ever so little greater than p_1 , the whole will dissolve in time.

If the mixture of salts is not moved, only a small amount of solution will form on the surface. But with stirring and grinding in this atmosphere, more solution will be formed, i.e., so much as contains the whole of B and so much of A as will give the ratio B/A of a solution which at the same time has a pressure p_1 and is saturated with A. If p is higher than p_2 , the surface film will extend inwards, giving finally a solution in which the salts are present in the ratio of the original mixture.

Series I.—Saturated atmosphere 23° C. Vapour pressure of water 21 mm.

Gains in weight of NaNO_3 + varying amounts of NaCl in atmospheres of different humidities.

		Weight of samples = 5g. Time in hours.					
		NaCl %					
From start	Interval	None	0.03	0.5	2.0	3.0	
22.5	22.5	0.055	0.064	0.085	0.096	0.148	
45.5	23	0.055	0.060	0.080	0.083	0.111	
69	23.5	0.049	0.062	0.067	0.103	0.110

138	21.5	0.065	0.064	0.090	0.104	0.106	
Totals		0.354	0.408	0.491	0.552	0.704	
Mg. per g. per hr.		0.51	0.59	0.71	0.80	1.0	

In this series the difference between the pressure p_s of saturated water vapour and of all possible solutions was considerable. The first deliquescence of the mixture samples was rapidly completed and not recorded, the subsequent gains recorded represent the rates of transfer due to the difference between 21 mm. (p_s) and the final pressures p_2 corresponding to solutions saturated with sodium nitrate and containing sodium chloride to potassium nitrate in the proportions of 0.08%, 0.5%, etc.

The mean rates of gain over several periods show a steady increase with increasing percentage of sodium chloride. Had the deliquescence pressure been due to solution saturated with respect to both salts the rates of absorption would have been con-

stant for all the mixtures. This was probably the case in the earliest stages of deliquescence.

Series II. Atmosphere over 37.7% sulphuric acid at 23° C. Vapour pressure 13 mm. Relative humidity 62%.

Time Intervals	None	NaCl			
		0.08	0.5	2.0	3.6
22.5	0.001	0.006	0.019	0.018	0.077
23	0.000	0.002	0.010	0.010	0.034
23.5	0.000	0.001	0.005	0.005	0.027
21	0.000	0.000	0.002	0.004	0.018
Totals	0.001	0.009	0.036	0.037	0.150

It would appear that in such an atmosphere there is a percentage of water capable of being held by sodium nitrate containing salt which depends among other things upon the percentage of salt. Series I, in the saturated atmosphere showed no slacking off of the rate of absorption, which would imply that in such an atmosphere the end condition would be when all the sample was in solution in the absorbed water.

In Series II the aqueous vapour pressure of the sulphuric acid used was nearly or quite equal to that of the solution of the pure sodium nitrate. With 0.08% of sodium chloride the solutions formed in the early stages with a fairly high ratio of chloride to nitrate have pressures which are lower than *p*. They absorb water, but the rate of absorption falls to zero in 69 hours, the solution formed by that time having a pressure nearly equal to *p*. With 0.5% of chloride the initial rate of absorption is greater, but again falls in time to a low value. The first solution which absorbs and deliquesces continuously will be that which, having a ratio of B/A equal to that of the original mixture and saturated with A, has at the same time a pressure below *p* (i.e., 13 mm. at 23° C.). This mixture will be recognised by the fact that the rate of absorption becomes constant, which had evidently not taken place even in the last experiment with 3.6% of chloride.

Series IV.—Atmosphere over 43.7% sulphuric acid. Vapour pressure 10 mm. Relative humidity 48%. Salt wet.*

Time Intervals	None	NaCl%			
		0.08	0.5	2.0	3.6
		Weight of water at start.			
19.5	0.128	0.165	0.216	0.208	0.285
27.5	0.086	0.145	0.182	0.197	0.286
25	0.042	0.072	0.143	0.188	0.288
25	0.014	0.040	0.121	0.181	0.291
25	0.000	0.019	0.091	0.183	0.294
10	0.008	0.015	0.080	0.183	0.206

*The numbers are those selected from the original paper, and hence are not consecutive. Those not selected are quite similar.

These results show the reversal of deliquescence. The wet salt was placed in an atmosphere of lower vapour pressure than its own. The loss should have been uniform in the case of the pure salt, but probably the slowness of diffusion in the solution interferes with regularity of loss. It is evident, however, that with about 2% of chloride there is very little loss, and with 3.6% a gain. Such a mixture could not be dried at this temperature unless the percentage of saturation of the atmosphere was reduced below 48.

Series V.—Saturated atmosphere at 13° C. Vapour pressure 11 mm.

Time Intervals	None	Percentage of salt.			
		0.08	0.5	2.0	3.6
24	0.047	0.051	0.070	0.080	0.077
23	0.047	0.043	0.054	0.055	0.070
25	0.047	0.052	0.065	0.064	0.072
Totals	0.141	0.151	0.189	0.199	0.219
Mg. per g. per hour	0.392	0.42	0.525	0.55	0.61

These results are similar to Series I, and show the constant gain of water from a saturated atmos-

phere at a lower temperature, at rates which vary also with the percentage of chloride. The method is particularly valuable at these lower temperatures, at which it is sometimes difficult to obtain concordant results with tensimeters.

University College, Nottingham.

DISCUSSION.

Mr. RICHMOND referred to the practical use which might be made of such measurements in the grinding and drying of salts and in laboratory drying processes. Specimens of the same salt often differed considerably in their tendency to deliquesce, strikingly illustrated by the behaviour of the common salt of the household. He would be glad of any information as to the best conditions for drying salts and for analysis.

Mr. WILKIE said that tetrahydrated potassium sodium tartrate presented some manufacturing difficulties. One sample might give a dry powder—another apparently similar a coherent mass. During grinding the chemically combined water was liberated, and the substance then probably crystallised again. In drying aqueous and hydro-alcoholic liquors to constant weight in water ovens did a higher temperature possess any advantages?

Mr. DUNFORD called attention to the fact that the drying of glue was much influenced by the state of the atmosphere, and that it was possible by suitable plant to reduce the time very much—an important factor in commercial success.

The AUTHOR, in reply to Mr. Richmond, said that cases differed so much that it was impossible to make general rules, but it seemed to him better where possible to dry at a relatively low temperature and to decrease the relative humidity of the atmosphere. The speed of drying in a vacuum was probably much greater than even in a rapid current of dry air. In answer to Mr. Wilkie, he did not desire to minimise the undoubted advantages of drying at higher temperatures, especially the gain in speed, but merely to point out possible danger of an unnecessarily high temperature. The drying of glue, not being a reversible process, could not be susceptible to exact measurements similar to those on salts, yet measurements would no doubt have some application. One application of a knowledge of the pressures of salt solutions to this industry might be in making atmospheres of controlled humidity.

Communication.

THE EFFECT OF THE ADDITION OF CERTAIN FATTY ACIDS ON THE INTERFACIAL TENSION BETWEEN B.P. PARAFFIN OIL AND MERCURY.

BY SHANTI SWARUPA BHATNAGAR AND WILLIAM EDWARD GARNER.

In a recent communication on "The theory and practice of lubrication" (J., 1920, 51 T), Wells and Southcombe have mentioned that Professor Lewis has measured the interfacial tension between oil and mercury.

The following measurements on the interfacial tension between B.P. paraffin oil and mercury and the effects of the addition of the organic acids on the metal-oil interface, began in October, 1919, at the suggestion of Professor F. G. Donnan, who definitely considered it as a problem of lubrication. Although the complete series of organic fatty acids has not been examined, on account of the difficulties in procuring some of them, the interest

created by the communication of Wells and Southcombe demands that our results should be published without any more delay.

Since there is no method yet known for measuring the solid-liquid interfacial tension, the liquid metal mercury was chosen. B.P. paraffin was selected on account of its definite composition and its high viscosity and high boiling point—properties which are good characteristics of an oil for lubrication purposes.

The fatty acids which were tried were pure except in the case of linolic acid, which was a technical product. The stearic and palmitic acids were purified by Kahlbaum, and the oleic acid was a pure sample obtained from the oil department of the Imperial College of Science.

The interfacial tension between mercury and the solutions of fatty acid in paraffin oil was determined by the dropping pipette method, already used by Donnan (*Z. physik. Chem.*, 1899, 31, 42), and later by his pupils. The bulk of the pipette was filled with carefully cleaned mercury up to a definite mark, and the head of mercury was always kept constant by an adjustable side-reservoir of mercury (fig. 1). This kept the rate of the falling drop quite constant. The end of the capillary dipping in the oil-solutions was made smooth and as regular as possible by grinding it very carefully with fine carborundum, the inner capillary being protected by sealing wax. The capillary was narrowed so that only two drops of mercury were formed in about a minute. It is necessary that the rate of formation of the drop should be very slow, otherwise the size and shape of the falling drop will not be regular, as pointed out by Rayleigh (*Proc. Roy. Inst.*, 1890—1892, 13, 857).

All necessary precautions were taken to prevent the entrance of dust into the apparatus.

Fig. 1.

The solutions of the fatty acids in B.P. paraffin oil were made up by weight in resistance glass bottles previously carefully cleaned. The acids formed a slight emulsion before they dissolved completely. In all cases the observations were taken only when a clear solution was obtained. Palmitic acid was not very soluble, and so only a few concentrations could be tried.

According to the theory of the instrument (Rayleigh, *Phil. Mag.*, 1899 (5), 48, 321), the surface tension is directly proportional to the weight of a drop. A large number of drops, never less than 20, was allowed to fall into a glass spoon (fig. 1), placed in the various solutions, and weighed after dissolving away the oil with carbon tetrachloride. The results so obtained were finally confirmed in each case by allowing about 50 drops to fall into a weighed quantity of the solution and noting the increase in weight due to the addition of mercury. The deviation between the values of the weight of the drop so obtained was never greater than 0.1%, the slightly variable results in the latter case being due to the drop of oil which is left on the end of the capillary after the experiment. This error was minimised as much as possible by wetting the end of the capillary with the same solution to the same level previous to the experiment.

The average weight of a drop has been calculated from at least 100 drops in each case. The results are shown in curves I., II., III. and IV. The surface tension of B.P. paraffin oil has been assumed to be 100 dynes per cm.

Curve I. represents oleic acid, II. stearic, III. linolic, and IV. palmitic acid. The curves for stearic, palmitic, and oleic acids are very similar in nature, especially at higher molar concentrations. The linolic acid employed was not pure, but in this case the diminution in the weight of the drop of mercury is very much greater than in the case of stearic and palmitic acids. The curve for oleic acid shows an inflexion point at a concentration of about 0.25%. Similar abnormalities have been observed by Donnan and also by Forch in case of nonylic acid.

The resemblance of these curves to those for fatty acids obtained by Langmuir (*J. Amer. Chem. Soc.*, 1919, 41, 1879), by plotting force in dynes per c.c. as ordinates against areas per molecule in sq. cm. as abscissae, is rather striking.

On the strength of this resemblance it might be possible to apply the views of Langmuir (*J. Amer. Chem. Soc.*, 1917, 39, 1865) in explaining the abnormal behaviour of oleic acid in dilute concentrations. Langmuir finds that an oleic acid film in

maximum extension is only half as thick as that of stearic or palmitic acid, so that when doubled in thickness by increasing the concentration (corresponding to the placing of a globule of oleic acid on the surface as tried by Langmuir), the film becomes of the same thickness as that of stearic and palmitic acids, and the cross-section of the molecules is also the same, with the result that the lowering in tension at higher concentration is also the same. It thus appears that the increased efficiency of a mineral oil as a lubricant to which an organic acid is added runs parallel with a lowering of tension at the metal-oil interface.

The authors are indebted to Professor F. G. Donnan, F.R.S., for suggesting this research and for the interest he has shown in the work.

Chemical Laboratory,

THE RECTIFIED PETROLEUM SPIRIT FROM THE TOLUENE-PETROL FRACTION OF BORNEO PETROLEUM, WITH A NOTE ON LABORATORY FRACTIONATING COLUMNS.

BY W. A. SILVESTER.

In a recent paper on the above subject (H. E. Evans, this J., 1919, 38, 401 T) it is stated that "it was found impossible to separate . . . further" by distillation the two main fractions which this petrol yields, notwithstanding that, *e.g.*, the "lighter" one ("distilling at 102°–103°") is apparently simply a mixture of heptane, bp. 98° and methylcyclohexane, b.p. 101°. The figures given below, obtained in working along similar lines, do not confirm this conclusion.

Although the experiments now reported afford incomplete support to the assertion, other experience leads the writer to state that the principles of fractional distillation are, as far as laboratory work is concerned, still imperfectly apprehended. The above citation appears to illustrate this, and the point will be considered further later.

The following are the relevant results of one series of experiments:—

(1) 4000 c.c. of the toluene-free petrol, sp. gr. at 15°/15° 0.748, was distilled up a "Hempel" column, 2 ft. high and 2 in. diameter (a lagged copper cylinder $\frac{1}{2}$ -filled with $\frac{1}{4}$ -in. lengths of glass tubing) at the rate of two drops per second, giving from 104°–108°, 1740 c.c., sp. gr. (15°/15°) 0.753 108°–112°, 1205 c.c., sp. gr. 0.746; above 112°, 950 c.c., sp. gr. 0.742 (bar. 766 mm.).

In a second series 4375 g. of the petrol (sp. gr. 15°/15° 0.7485) was more carefully distilled, through a screened all-glass 8-section Young "evaporator" still-head, 3 ft. high and about 1 in. average diameter, giving, again on a single fractionation:—

Range.	Weight, g.	Sp. gr. 15°/15°.
90° to 102°	59	0.752
" 104°	69	0.752
" 106°	948	0.750
" 108°	992	0.748
" 110°	790	0.746
" 112°	429	0.742
" 114°	342	0.739
" 116°	290	0.736
" 118°	191	0.736
" 120°	234	0.737
" 121-6°	146	0.743
Residue	41	(bar.: 762 mm.).
Total	4355	loss therefore 20 g. or 0.5%

In this and the following experiments the temperatures were registered by a carefully calibrated thermometer with 0.2° divisions and corrected for stem exposure. All specific gravities were taken with a specially calibrated small hydrometer and were from time to time checked pycnometrically.

The above fractionations compare as follows (percentages in round numbers):—

Range.	Hempel 2-foot, by wt.	Young evaporator 3-foot, by wt.
104°–108°	44%	47%
108°–112°	30%	26%
Above 112°	25%	26.5%

This is a good result for the much shorter Hempel column.

Working on a somewhat heavier sample of petrol (sp. gr. 15°/15°: 0.7483), Evans's first distillation (the only one available for comparison) was made through a 12-pear Young column. The results compare thus with the second series above:—

Range.	12-pear. by vol.	8-section "evaporator," by vol.
90°–108°	35%	47%
108°–115°	38%	35%
115°–120°	25%	18%

Thermometric differences probably account for some of this disagreement.

All the above material, from both fractionations, save small quantities used meanwhile for other tests, was again twice *cumulatively* fractionated up the "evaporator" still-head, giving products showing the following boiling-point-specific-gravity relationships:—

Range.	Sp. gr.	Range. (Bar.: 760 mm.).	Sp. gr.
100° to 101°	0.755	111°–112°	0.743
" 102°	0.756	" 113°	0.742
" 103°	0.757	" 114°	0.741
" 104°	0.7565	" 115°	0.740
" 105°	0.755	" 116°	0.738
" 106°	0.754	" 117°	0.737
" 107°	0.752	" 118°	0.737
" 108°	0.750	" 119°	0.7365
" 109°	0.748	" 120°	0.737
" 110°	0.747	" 121°	0.740
" 111°	0.745	" 122°	0.741
		" 123°	0.741
		Residue	0.755

* Max. volume per degree.

One point is clearly indicated by the above figures and could only have been brought out by checking continuously the distilling range against the specific gravity—that is that repeated cumulative fractionation would have further resolved the mixture and separated the respective paraffinic and naphthenic components of the two main fractions. This is only to be expected in spite of the small differences in boiling-point. A still further separation of methylcyclohexane (hexahydrotoluene) from the 102°–103° fraction was, in fact, achieved, but the data obtained are not now at hand. Some evidence, however, is yielded by the following figures, which also demonstrate the absence of any noteworthy constituent of boiling-point between 105° and 115°. These are the results of tests made to give a definite index of the homogeneity of the different fractions. 100 c.c. of each fraction was distilled in the standard Engler apparatus for petrol tests, and the volume percentage distilling up to, between, and above the original limits of the fraction registered:—

Fraction.	Vol. % distilling between original limits, <i>i.e.</i> , in original temperature range.
102°–103°	56
103°–104°	504
104°–105°	424
105°–106°	384
106°–107°	31
107°–108°	26
108°–109°	26
109°–110°	23½
110°–111°	18
111°–112°	26
112°–113°	26½
113°–114°	26½
114°–115°	23½

The lack of homogeneity in even the best fraction—that boiling from 103° to 104°—is here very apparent, and the present writer is at a loss to understand how Mr. Evans came to his conclusion.

The presence of methylcyclohexane in the petrol was proved by isolation of its chloro- and nitro-derivatives.

To return to the question of fractionation. In this branch academic and laboratory practice is still far behind that of the works. Separation of the components of a boiling liquid mixture in a fractionating column takes place (1) by fractional condensation by loss of heat through the walls of the column, and (2) by interchange of heat between the rising vapour and the returning condensate whereby the "heavy" constituents of the vapour condense out whilst the "lighter" parts of the condensate revolatilise. On the works scale the two processes are kept separate; fractional condensation is regulated, and kept under control, by the "dephlegmator"—a small reflux condenser at the top of the column. The condensate thus provided is brought into intimate contact with the rising vapour by a bubbling device. The whole process therefore is of great efficiency. In the laboratory, on the other hand, such apparatus as is commonly used, except the columns of Hempel and Linnemann and their modifications, mainly relies on fractional condensation to effect its object. Such contrivances as those of Glinsky, Young ("pear" and "rod-and-disc"), Dufton (J., 1919, 45 T), and many others simply cause the vapour to take a tortuous passage and depend almost entirely on external—uncontrolled—cooling to bring about the desired separation. Naturally, some heat-interchange between vapour and condensate also takes place, but to nothing like the degree needed for efficient fractionation.

A simple and easily constructed laboratory-size column, in which there is proper provision for heat-interchange is that devised long ago by Hempel. The value of a bead packing in small gas-washing devices is well recognised, and the only reason the writer can assign for the unpopularity of the Hempel still-head is its tendency to choke and "puke." This defect is overcome by proper attention to the construction. If such a column is lagged and surmounted by a constant temperature dephlegmator, so as completely to reproduce works practice in miniature, most efficient results are obtained (Washburn, J. Ind. Eng. Chem., 1920, 19, 73).

The superiority of the Hempel column, even as commonly used, is demonstrated both by the writer's and Mr. Evans's results and also by comparative tests reported from time to time (e.g. Friedrichs, Z. angew. Chem., 1919, 32, 340; Rittman and Dean, U.S. Bureau of Mines Bulletin on Analytical Distillation of Petroleum; Young, Chem. Soc. Trans., 1899, 679). In other respects these comparative tests are of little value. The efficiency of "fractional-condensation" devices obviously depends largely on the thickness and area of the walls, as well as on the height; this is usually overlooked in

reporting comparisons. It is to be regretted that any standing is given to the fantastic arrangements of bulbs and bends, such as are sold as Le Bel-Henninger etc. still-heads.

Finally, in the Hempel device, as ordinarily used, it is evident that a not inconsiderable proportion of the fractional condensation results from absorption of heat by the packing material. It would be expected, therefore, that, *ceteris paribus*, a packing of high would be more efficient than one of low specific heat. This appears to be illustrated by Mr. Evans's results (*loc. cit.*) A steel (sp. ht. 0.1158, heat capacity for 1 c.c. 0.915 cal per 1° C.) packing proved more efficient than a lead one (sp. ht. 0.0314, heat capacity for 1 c.c. 0.358 cal per 1°). The decrease in size of the balls—and therefore increase in surface—and the relative increase in mass per c.c. would also take part in the effect.

THE DETECTION OF NATURAL BARYTES IN LITHOPONE ETC.

BY S. STEWART, F.I.C.

Lithopone, Orr's zinc white, and other pigments composed essentially of zinc sulphide and barium sulphate should contain the latter only in the precipitated form. Inferior qualities sometimes contain natural barytes, to the detriment of their covering power, owing to the large size of the particles of barytes as contrasted with those of the precipitated sulphate. Its opacity is less, and although, when used as an ingredient in ordinary paints, this is perhaps of secondary importance, it becomes a matter of serious consideration when used for some other purposes; for example, in making white inlaid linoleum the use of lithopone containing natural barytes leads to the production of a yellowish white. The microscope affords a convenient means for differentiating between natural and precipitated barium sulphate. The test is carried out as follows: A minute portion of the sample is spread on a microscope slide with a drop of water, dried, and examined with a $\frac{1}{2}$ in. or $\frac{3}{4}$ in. objective, the diaphragm being closed so as to give a dark background. If only precipitated barium sulphate be present, it appears as a very fine powder composed of minute crystals of uniform size, whereas if there is an admixture of natural barytes, even when very finely ground, transparent irregular pieces of greater size will appear. The certainty of the method is enhanced if the zinc sulphide present in the lithopone be first removed by treatment with dilute hydrochloric acid and potassium chlorate and the insoluble residue examined as above.

This method has been in use for 22 years in the laboratory of Messrs. Michael Nairn and Co., Ltd., Kirkcaldy, to whom the author's thanks are due for permission to publish it.

PROCEEDINGS OF THE

THIRTY-NINTH ANNUAL GENERAL MEETING,

Newcastle, July 13th, 1920.

The thirty-ninth annual general meeting of the Society was held in the Chemical Lecture Theatre of Armstrong College on July 13.

THE LORD MAYOR OF NEWCASTLE (Councillor Walter Lee, J.P.), in extending to the Society a hearty welcome to the city, assured them that they in Newcastle fully realised the importance of the chemical industry and he hoped from the scientific, practical, and social points of view that their meeting would be a great success. He looked to the industry they represented to take a great part in the work of reconstruction now proceeding. The country was now beginning to settle down and there was a feeling that the boom was ending. There would be the question of providing employment for many people, and he looked to science to do a great deal for industry in that direction.

SIR THEODORE MORISON, Principal of Armstrong College, in welcoming the Society to Armstrong College, said that it was a source of satisfaction to him that they had chosen the College as their meeting-place. The association of the Universities with industry was one of the outstanding features of the present time. Industry was becoming more and more alive to the importance of education, and particularly university education, and the universities were also becoming alive to the importance of industry. At one time the universities had rather held aloof from the practical side of life, and it was due particularly to the chemical faculty that the division between universities and industries had been broken down. In every faculty of the universities the professors were now bringing forward their contributions to industry; perhaps the most remarkable thing of all was to see the faculty of philosophy, recently discovering that one of its branches—psychology—might be of use to industry.

PROF. LOUIS, in thanking the Lord Mayor and Sir Theodore Morison, said:—In the regretted absence through illness of the President, it devolves upon me to thank you in the name of the Society of Chemical Industry for the welcome that you have accorded us on the occasion of our visit to Newcastle-on-Tyne. I do this with the utmost pleasure, more particularly because I feel that such a two-fold Civic and Academic reception is one that peculiarly befits the aims and objects of our Society, a Society whose principal object has always been to foster the applications of science to industry. You, my Lord Mayor, have welcomed us as the chief Civic representative of a great city renowned for its industry and enterprise, the capital of a district second to none in the United Kingdom for industrial development, and you, Sir Theodore Morison, have been good enough to welcome us as the head of the principal educational and scientific institution of this city. We are grateful for the manner in which you have thus united to bid us welcome here, but I may be allowed to say that I see in this joint reception of the Society of Chemical Industry something more than a manifestation of the traditional North-country hospitality; I hail it as an omen of the new era that is developing around us and which, properly understood, will certainly make for the continued prosperity of Tyneside. As one who has lived here for a quarter of a century in touch with a certain number of leading industries of the district, I think that I am justified in voicing my conviction that the local industries have never,

until perhaps quite recently, duly appreciated the advantages that they could derive from a more intimate contact with the modern applications of science. North-country manufacturers have indeed not availed themselves as much as they might have done of the resources of scientific technology. There are, of course, various reasons that have contributed to this result, and I venture to suggest that one cause, generally overlooked, is to be found in the many admirable qualities of the Tyneside working man. I have been engaged in work and in the management of men in many quarters of the globe and can truthfully say that for skill, intelligence, and resourcefulness the North-country workman has no superior anywhere. It is this fact that has given rule-of-thumb methods a longer lease of life than in most other places and has enabled the managers of North-country works to dispense with scientific methods and scientific control of operations for a longer time than could have been the case were these operations conducted less skilfully. The severe industrial stress due to war has, however, forced forward a change of view in this as in so many other respects, and the need for intensive production under altered conditions has brought home the importance of applying the methods of modern science, and manufacturers are coming to perceive that the sphere of the chemist and the physicist may be largely extended. I could give a long list of Tyneside firms, which half a dozen years or so ago took but little heed of these sciences, but which to-day recognise the chemical laboratory as an essential part of their establishments, and will readily admit that they have made no better investment than the money spent on this portion of their equipment. It is becoming daily more evident that the after-war struggle will be in its way as strenuous as was that of actual warfare, and that we can hold our own only by developing and extending the scientific and technical methods that brought us victoriously through the war. That you, my Lord Mayor, and you, Sir Theodore Morison, have combined to welcome to Tyneside a Society that stands pre-eminently for the applications of high scientific methods to industry is evidence that you appreciate the importance of these principles in this district, and we sincerely hope that the visit here of our Society will contribute its share towards stimulating interest in a more intimate union between science and industry in all its branches, particularly in the highly diversified series of industries which we group together under the head of "Chemical Industry," with which we are here most closely identified.

THE LORD MAYOR briefly responded to a vote of thanks accorded by acclamation. PROF. LOUIS then took the chair and the formal business of the meeting was proceeded with.

The minutes of the last annual meeting were taken as read.

It was unanimously agreed, at the suggestion of the Chairman, to ask the Secretary to send to the President, in the name of the Society, a telegram expressing their sympathy with him in his illness and their hope that he would have a speedy and complete recovery.

Dr. G. S. Weyman and Mr. A. Short were appointed scrutineers of the ballot for the election of Council, and the ballot was declared closed.

REPORT OF COUNCIL.

During the year the Council has held 10 ordinary meetings, and the following Committee meetings have been held: Finance Committee, 18; Emergency Committee, 4; Publications Committee, 8; Transactions and Abstracts Sub-Committee, 24; Review Sub-Committee, 24; Annual Reports, 5; Sub-Committee on Weekly Journal, 1; Literary and Libraries Committee, 2; General Purposes Committee, 5; Technical Research and Allied Societies Committee, 9.

The number of members on the Register is now 5612, as compared with 5236 last year. Since the last Annual Meeting 562 members have been elected, 71 former members have been restored to membership, and the losses have been 257.

The Council regrets to record the deaths of 46 Members (of whom 13 were Original Members), viz.:—

Joseph Barrow, Harry Broadbent, John R. Brooke, Prof. Adrian J. Brown, Arthur H. M. Brown, Thomas Buggy, Paul Butler, F. J. R. Carulla, Herbert S. Coleman, Percy W. Copeland, W. J. Cousins, W. J. Cowan, Wm. B. Cowie, Joe Frost, John C. Galletly, Dr. Frank B. Gallivan, Holbrook Gaskell, George H. Graves, Dr. Harold C. Greenwood, Dr. J. Grossmann, C. E. Groves, Edwin Haviland, Robert F. Jenkins, Wm. A. Johnston, Walter R. King, F. E. Lott, Dr. Edward G. Love, J. S. McArthur, Dr. Rudolph Messel, John Metcalf, Dr. B. More, Thos. Pierre Morson, Wm. Letts Oliver, Prof. L. T. O'Shea, T. W. Pilley, W. Cobden Samuel, Robert C. Scafe, Kenneth W. Smith, Watson Smith, William G. Smith, J. Fleming Stark, I. Frank Stone, Herbert S. Sutton, John C. Umney, Dr. Elwyn Waller, Leonard E. Weldon.

Dr. R. Messel, F.R.S., was President in 1911–12, and again in 1914, and held the office of Honorary Foreign Secretary from 1913.

Mr. Watson Smith was Editor of the Journal from its commencement until 1914.

Mr. John Gray's year of office as President of the Society expires after the Annual General Meeting, and as he was unable to accept nomination for a second year the Council has nominated Sir William J. Pope, K.B.E., F.R.S., as his successor in office.

Mr. D. Lloyd Howard found it necessary, owing to pressure of business engagements, to resign the post of Honorary Treasurer to which he was elected in 1918, and Mr. E. V. Evans, one of the Vice-Presidents, has been appointed his successor.

Professor Henry Louis, a Vice-President and former President, has been elected Honorary Foreign Secretary in succession to Dr. R. Messel, deceased.

Dr. E. F. Armstrong resigned the office of Vice-President, retaining a seat on the Council in virtue of his being Chairman of the Liverpool Section, and Mr. S. R. Trotman was elected to fill the vacancy. Mr. L. P. Wilson was elected a Vice-President in room of Mr. Evans.

Mr. John Gray has been nominated a Vice-President, and to the other vacancies caused by the retirement of four Vice-Presidents Mr. D. Lloyd Howard, Dr. Stephen Miall, and Mr. Edwin Thompson have been nominated.

Four ordinary members retire from the Council, and to fill the vacancies thus created six nominations have been received; a ballot will therefore be taken.

The following chairmen of local sections retire: Mr. C. E. Sholes (American), Mr. Q. Moore (Glasgow), Prof. P. P. Bedson (Newcastle), Mr. F. H. Carr (Nottingham), and Mr. W. McD. Mackey (Yorkshire). The following have been elected to succeed them respectively: Mr. S. R. Church, Mr. J. H. Young, Dr. J. H. Paterson, Mr. J. H. Dunford, and Mr. S. H. Davies.

Prof. J. W. Hinchley retires from the chairmanship of the Chemical Engineering Group, and Mr. J. Arthur Reavell has been elected his successor.

Dr. Stephen Miall has resigned the Honorary Secretaryship of the London Section, and has been succeeded by Dr. G. W. Monier-Williams.

The Council desires to express its cordial thanks to the retiring officers for their services to the Society, and has conveyed to the relatives of the late Dr. Messel and of the late Mr. Watson Smith its high appreciation of the valuable work done by them respectively.

The President during his year of office has visited the following Local Sections of the Society and held informal meetings with the Committees:—Birmingham, Edinburgh, Glasgow, London, Newcastle, and Yorkshire. He has also met the Committee of the Chemical Engineering Group. On each occasion he was accompanied by the General Secretary. The Council is very pleased to know that these visits have given much satisfaction to the local committees and feels sure they will be productive of great benefit to the Society.

An invitation was received from the Newcastle-on-Tyne Section to hold the Annual General Meeting (1919) in Newcastle. For the reasons stated in last year's Report of Council this invitation was not accepted, but it gave the Council much pleasure to receive a renewal of the invitation for 1920, which has been unanimously accepted.

A cordial invitation has been received from the Canadian Section to hold the Annual Meeting for 1921 in Montreal, and the Council recommends its acceptance.

It was decided in November that for the further period of twelve months no enemy aliens should be admitted to membership of the Society.

The Committee of the London Section has promised to give a donation of 200 guineas to the Society out of funds remaining over from the Annual General Meeting last year. The Council much appreciates this generous gift.

The Audited Balance Sheet and Statement of Income and Expenditure for the year ending December 31, 1919, which have already appeared in the Journal for June 30, will be laid before the meeting.

The Amended By-Laws recommended by the Council for adoption, and which have been circulated among the members, will be submitted at the meeting.

The Journal for 1919 contained 1866 pages of text (Review 486, Transactions 412, Abstracts 968), compared with 1612 in 1918. Advertisements: 1298 pages in 1919; 1464 pages in 1918.

Volume IV. of the Society's Annual Reports on the Progress of Applied Chemistry was published this year, and the purchase of the new volume has been accompanied by a considerable number of orders for Vols. II. and III. Volume I. has been out of print for more than a year.

The preparation and publication of a collective index to the Journal from 1906 to 1919 inclusive has been under consideration, but, having regard to the probable cost involved, it was decided that at the present time it is impossible for the Society to undertake the work without substantial financial assistance.

A proposal that the Journal should be published weekly has been discussed, but in view of the present financial position of the Society it was resolved that the whole question be deferred for the present.

Representations have been received that the present system of charging authors the cost price for reprints of papers published in the Journal is objectionable, and that it acts as a deterrent to would-be contributors. The Council is in full agreement with these views and has decided that the former plan of giving a certain number of

free copies should be reverted to as soon as the Society's financial position permits.

Arrangements have been made to supply the press with items of news of general interest relating to chemical industry. It is hoped by this means to make the Society's activities more widely known.

The Council earnestly invites the co-operation of all members of the Society in maintaining and extending the supremacy of the Journal as the premier non-trade British publication devoted to chemical industry.

Mr. G. H. Ford, M.Sc. (Manchester) has been appointed Assistant Editor of the "Review" Section of the Journal.

A scheme drawn up by the President, Mr. John Gray, for the setting up of a number of standing committees has been adopted with the object of facilitating the work of the Council and of providing an appropriate series of committees to which matters requiring special consideration can be at once remitted. A list of these committees, with the names of the chairman and members in each case, is given in the Journal, vol. 39, p. 85 B.

In the absence, through ill-health, of Dr. Carpenter, Chairman of the Finance Committee, the Council has appointed Dr. E. F. Armstrong interim Chairman.

Professor Henry Louis has been elected a member of the Finance Committee in place of Dr. Messel, deceased, and Dr. Lovinstein has resigned his membership of it.

Mr. J. Arthur Reavell was co-opted to the Transactions and Abstracts Sub-Committee of the Publications Committee as representative of the Chemical Engineering Group in the absence, through ill-health, of Prof. J. W. Hinchley.

Prolonged and serious consideration has been given to the financial position of the Society. The Income and Expenditure accounts for the years 1918 and 1919 show deficiencies of £3145 and £2353 respectively. In order to wipe off the former, several of the Society's investments had to be realised, and a similar course will have to be adopted for the purpose of clearing off the latter. The deficiencies have been due to the enormous increase in the cost of printing and paper, and the Council, realising the seriousness of encroaching further on the Society's reserve funds, has, after much deliberation, decided that the Annual Subscription must be increased from January 1 next. A resolution regarding this will be placed before the meeting. To provide for the case of young persons applying for membership a scheme has been devised under which such persons will be admitted at a lower subscription than that payable by ordinary members. This scheme will be laid before the meeting for adoption.

Realising the urgent importance of deriving as large an income as possible from the advertisements in the Journal the Council decided to take this business into its own hands and gave Messrs. T. G. Scott and Son the required six months' notice, which expired on May 31. Mr. P. Le Good has been appointed Advertisement Manager, and he, along with his staff, are accommodated in the Society's offices.

A resolution was unanimously passed at an Extraordinary General Meeting of the Society, held on October 23, declaring that the Chairman and Honorary Secretary of a Subject-Group shall be *ex officio* members of the Council; and this was unanimously confirmed at a similar meeting held on November 20. (See Report of Council, 1919.)

The Council has awarded the Society's Medal for 1920 to Monsieur Paul Kestner in recognition of his distinguished services to chemical industry. (See Journal, vol. 39, p. 157 A.)

Through the generosity of Messrs. Cross and Bevan, and of Sir T. P. Latham, Bart., of Weybridge, a prize is again offered for an essay on "The Interconnexion of Economic Botany and

Chemical Industry"; also a fellowship endowment. (For full particulars see Journal, vol. 38, p. 471 B.)

It is gratifying to know that members of the Society are taking advantage of the facilities offered them by the Chemical Society for using its Library and borrowing books from it. The Council has renewed for 1920 its donation towards the expenses incurred in connexion with the Chemical Society's Library Extension Scheme.

The London Section appointed a Committee, of which Professor J. C. Philip was Chairman, to report on the steps which should be taken in order to standardise the application of the Refractometer to industrial and scientific purposes, and its report was published in the issue of the Journal for December 15.

The Council has received from the Chemical Engineering Group of the Society a resolution requesting it to take up consideration of Standardisation on a wide and comprehensive basis in connexion with apparatus and materials in the Chemical Industry to which standardisation can properly be applied. The Council considers that this subject is one of great importance, and it is securing the co-operation of the Association of British Chemical Manufacturers and of the British Engineering Standards Association in dealing with it.

In the interests of the members of the Society who are Chemical Engineers the Council has taken an active interest in opposing the Civil Engineers (Registration) Bill promoted by the Institution of Civil Engineers. Having regard to the admitted impossibility of the Bill passing in the present session of Parliament, it has been decided to take no further action at present.

The compilation of a Card-Index of the Catalogue of Publications referred to in Chemical Literature, and the Libraries of the U.K. in which they are to be found, has now been brought up to date by Dr. Holt, and has been deposited in the offices of the Society. Further particulars regarding this will be given in an article which it is hoped that Dr. Holt will shortly contribute to the "Review." The Council appreciates very highly this valuable work which Dr. Holt initiated and has brought up to date.

Substantial progress has been made in arranging and cataloguing the stock of books and journals belonging to the Society, and an anonymous donor has contributed the sum of £25 towards the expense of the work.

The Report of the Empire Sugar Supply (Technical) Committee, and the Report of the Committee on the Standardisation of Laboratory Glassware were published in the issue of the Journal for August 15. (See Report of Council, 1919.) Each of these Reports has been reprinted.

The draft rules of the Federal Council for Pure and Applied Chemistry provide that the constituent bodies shall contribute to the expenses of the Federal Council (including the agreed contribution to the International Union of Pure and Applied Chemistry) on a membership basis. The Society's contribution will be £100 per annum, and this has been agreed to. (See Report of Council, 1919.)

The Grasselli Chemical Co. presented to the Society a framed copy of the medal which they have founded in connexion with the American Section. (See Report of Council, 1919.) The gift was accepted with thanks to the donors.

The Imperial Mineral Resources Bureau submitted a scheme to establish a complete system of abstracting publications dealing with the entire subject of mineral products, and suggested that a committee should be formed to consider the best means for carrying this into effect; it was also their intention to set up other committees which should direct their attention to special subjects and classes of mineral products. The Council, on the invita-

tion of the Bureau, nominated two representatives to the "Abstracts" Committee and one representative to each of certain other committees.

A communication was received from the University of London requesting the Council to suggest names of members to form a committee representative of the Chemical Trades to examine its Scheme for Degrees in Commerce. It was considered desirable that such a committee should comprise representatives both of the Society and of the Association of British Chemical Manufacturers, and this suggestion was approved by the University authorities.

A list of the Society's representatives on outside bodies is given in the Journal, vol. 39, p. 85 R. To this list the following should be added:—

Imperial College of Science and Technology (Board of Governors):—Dr. Charles Carpenter.

London University Degrees in Commerce.—*Chemical Trades Committee*:—The President, Dr. Carpenter, Mr. D. Lloyd Howard, and Dr. C. A. Keane, representing the Society; Sir John Brunner, Bart., and Mr. C. A. Hill representing the Association of British Chemical Manufacturers.

Mr. W. F. Reid was appointed the Society's representative on the Committee of the Department of Import Restrictions. The work of the Committee has since been taken over by the permanent officials of the Board.

A communication was received from the President of the American Chemical Society inviting the Council to appoint a Committee on Nomenclature, Spelling, and Pronunciation to co-operate with the corresponding Committee of the American Society. Prof. G. T. Morgan, Mr. T. F. Burton, and Dr. E. H. Tripp were appointed such a Committee, to co-operate with the similar Committee of the Chemical Society of London.

Consideration has been given to a communication from the Conjoint Board of Scientific Societies pointing out the serious handicap from which the nation suffered in the early years of the war in respect to the application of science to war problems and the desirability of approaching the Admiralty and War Office with the object of establishing a more satisfactory and permanent basis for the application of science to the problems concerned in view of future wars. The Board regards it as essential that continuous research by co-operation between the Services and individuals engaged in scientific research should be established with a view to the application as soon as possible of new discoveries and principles to war problems, and that facilities for the mobilisation of a scientific staff without delay and in the most efficient manner should be provided. The Council is fully in accord with the views and proposals of the Board, and has submitted certain suggestions bearing on the scheme.

A communication was received from the National Union of Scientific Workers regarding the question of making representations to the Lords of the Treasury for the purpose of obtaining concessions in respect of the assessment for income tax of scientific workers, along with a suggested form of petition, and the Council has expressed its sympathy with the proposals submitted.

The above report, which was taken as read, was adopted on the motion of the Chairman, seconded by Dr. J. T. Dunn.

HON. TREASURER'S REPORT.

MR. D. LLOYD HOWARD, the retiring treasurer, moved the adoption of the statement of account and balance-sheet (see Journal of June 30, 1920). He had again to report a deficit, though not so large a deficit as in 1918. At the last general meeting he was able to announce that the income from advertisements was coming in at the rate of £10,000 a year, and he was now glad to say that the income for the whole year had exceeded £10,000. That

income they hoped would be increased when the new arrangements made with regard to advertising came into full operation. As to the general position, they had again been compelled to borrow money from the bankers; they were able to borrow sufficient to cover the year's expenditure without realising further securities, and though borrowing was bad, selling was worse. Later they would have resolutions put to the meeting dealing with the question of raising the subscription. It was not for him to go deeply into that subject except to say that while the financial situation was serious he did not consider it to be by any means desperate, and he believed that if the meeting adopted the recommendations of the Council the Society ought to have every prospect of winning through and being again on a sound financial basis. As retiring Treasurer he wished to explain why he did not seek re-election. He had taken office on the death of the late Hon. Treasurer in 1918, and he took the opportunity of thanking his colleagues on the Finance Committee and the Council for the great help they had always given him and for the unvarying kindness and consideration always shown him. They had made his term of office extremely enjoyable in an anxious time. Those not on the Council ought to know the enormous debt they owed to all the officers, especially to their last three Presidents, Dr. Carpenter, Prof. Louis, and Mr. Gray. The initiation and successful working of the Finance Committee and the drafting of the scheme of committees now in operation was due to those three Presidents. His reason for resigning his position as Hon. Treasurer was exactly as stated in the report, namely, that the demands of his business did not give him sufficient leisure to devote that amount of time to the treasurership that he felt he ought to give. He was entirely in accord with the policy of the Finance Committee in every respect, and deeply regretted that his engagements would not permit him to continue in office. He formally moved the adoption of the report.

MR. E. V. EVANS, the Treasurer-elect, in seconding the adoption of the report, said he was sure that he would be voicing the feeling of the members in assuring Mr. Howard of their appreciation of the services he had rendered to the Society. He had set his successor a very high standard to live up to. The main object of the Society of Chemical Industry was to supply its members with a periodical account of the progress of the industry and to keep industrial chemists in touch with the march of applied chemistry. The Journal was the life-blood of the Society, and the Council was therefore most anxious that the committees responsible for the work should keep it at the highest possible scientific standard. The income of the Society was largely dependent upon the popularity of the Journal, and upon its popularity depended the membership and its use to advertisers. They received criticisms of the Journal from time to time, and he assured them that criticism was always highly appreciated. The policy of the Society was to attempt to cater for the chemical manufacturer and commercial chemist as well as for the academic chemist, and all their efforts must be towards making the Journal increasingly interesting and useful to chemists and chemical manufacturers. Since their expenditure had exceeded their income, it was necessary to increase the subscriptions. The only alternative to that would be to decrease the effectiveness of the Society, but that would be disastrous policy. He could not be a party to such a procedure, and would, personally, rather see the Society go down in honourable bankruptcy—which, by the way, was impossible—than its value be detracted. He had much pleasure in seconding the adoption of the report.

The report was unanimously adopted, and a vote of thanks was passed to the retiring Treasurer by acclamation.

THE ANNUAL SUBSCRIPTION.

THE CHAIRMAN said, that the next item on the agenda, the proposed increase of subscriptions, was perhaps the most important of all. In a sense the meeting had already agreed to it by adopting the Report of the Council, but he hoped the matter would be taken independently and discussed on its own merits. The position was, simply put, that they were spending more than they were getting. The Society was in a flourishing condition so far as concerned the influx of new members, but every new member cost more than he paid. Obviously such a state of affairs could not continue. The Finance Committee and the Council had carefully studied the whole position, and had come to the conclusion that the proposed increased subscriptions would just about cover the year's expenditure by rigid economy and care, though it would not leave any surplus. He formally moved the following resolutions:

- (1) That the annual subscription payable by members be £2 10s. from January 1, 1921.
- (2) That the Life Composition Fees be increased from £30 and £25 to £40 and £35 respectively.
- (3) That a member joining under the age of 25 shall be entitled to pay a subscription of £2 per annum until attaining the age of 25, or for three years from the date of election, whichever is the longer period; but subject to the provisions that his application for membership must be accompanied by (1) satisfactory evidence of age, and (2) a declaration that he is not joining the Society as a nominee of any firm or corporation, but solely in his own interests as an individual member.

DR. E. F. ARMSTRONG, in seconding the resolution, said that the Council had not put them forward lightly. The question had been considered for over twelve months. A year ago they had deferred bringing it forward because, like other people, they had been optimistic that things would improve. That optimism had not been justified, and the consequence was that the Council had found it necessary to put forward these resolutions. The Council had taken up a firm position in refusing to allow the standard of the Journal to fall, and he hoped they would all support the Council. He did not think a reduction of expenditure was possible to any appreciable extent. The increase in expenditure was caused by matters over which they had no control—paper and printing costs. The only cutting down of that expenditure was by reducing the size of the Journal—a policy which he felt sure they would agree was a shortsighted one. The decision to increase the subscription had not been come to without much consultation with the Local Sections.

DR. L. F. GOODWIN suggested that more members might be obtained in Canada and in the United States by allowing members there to come in at a lower rate of subscription in order to some extent to meet the competition of the American Chemical Society.

THE CHAIRMAN pointed out that Canadian members already were costing more than the Society received from them. If they only charged the Canadian members the net cost of the Journal the Society would be out of pocket. The ordinary expenses had to be borne by Canadian members as by others. Any representations of the kind suggested by Dr. Goodwin would, however, receive careful consideration by the Council.

ALTERATION OF BY-LAWS.

The proposed alterations to By-laws, as circulated in the Journal, were moved by the Chairman,

who briefly reviewed the main points of these alterations.

DR. STEPHEN MIALI seconded, and the alterations were agreed to without discussion.

PRESENTATION OF MEDAL.

In presenting the Medal of the Society to M. Paul Kestner, Prof. LOUIS said:—"None of the duties devolving upon me to-day affords me greater pleasure than that which I am next called upon to perform, namely, the presentation of the Medal of our Society. M. Kestner, in the name of the Society of Chemical Industry I have to ask your acceptance at my hands of the Medal of the Society. You are aware that the Society presents this Medal to chemists who have achieved distinction in one or other of the numerous branches of our many-sided subject, and the list of our Medallists shows a long line of illustrious names, to which we now take pride in adding your own. Your work has lain essentially in that difficult and complex branch of the subject which we are learning to speak of as chemical engineering, and I may be allowed to express the hope that the award of this Medal to you may be taken as an indication of the importance that the Society attaches to this particular branch of the subject and as an encouragement to those who are devoting their energies to its development. The admirable results that you have achieved and the inventions with which you have enriched chemical technology are too well known to make it necessary for me to do more than refer to them here in very few words.

"In the first place I would like to mention the improvements that you have introduced in the appliances for acid manufacture, such as your fans for acid towers and for acid gases and your automatic acid elevator, an appliance that played an important part in chemical industry during the war.

"Here on the Tyne we are naturally interested especially in all that appertains to fuel and fuel economy, and in the latter respect the climbing film evaporator, with which your name is associated, takes particularly high rank. It has already shown itself capable of effecting remarkable economies in the consumption of fuel required for evaporation, and we are looking forward with great interest to those developments of the principle which you have in hand, as, for example, the application of the climbing film principle to water tube boilers. In the same way we are looking forward with interest to the applications of the same principles to your new methods of sugar manufacture, to which I understand you are devoting your attention at the moment. Having regard to the world shortage of this essential article of food, we can only hope that in the public interest you will persevere with this interesting work and that your labours may be crowned with complete success.

"In addition to all this mass of technical work which you are carrying on with such energy, I should like to mention some of your other activities in connexion with chemical industry, such as the prominent part that you have taken in founding in your own country the sister society to our own, the Société de Chimie Industrielle, and in firmly establishing it in a few years as one of the foremost French technical societies. You have played a great part in helping forward the formation of the Inter-Allied Association of Chemists, which will tend to draw yet closer together the scientific and technical resources of the nations which have devoted these to a common cause in the interests of the world's civilisation. Finally, whilst emphasising the fact that this Medal is a tribute to your own eminent personal merits, I may be allowed to express the hope that the chemists of both our nations will recognise in the homage that we thus pay you the earnest desire of both to continue in

times of peace the close and cordial co-operation that led us through the bitter stress of war to its ultimate triumphant issue."

M. PAUL KESTNER, after receiving the Medal, said that in granting the Medal of the Society to a foreigner the Society had not altogether departed from tradition. Not only was he an old member of the Society, but he was an old friend of Great Britain. He had always been a fervent admirer of Great Britain, and he was quite certain that he owed what success he had attained to the knowledge he had gained in an intimate connexion with this country—a connexion of over 30 years. Truly he had sat at the feet of the British men of science and British manufacturers. He felt he was one of their pupils. The honour which they had conferred on him was totally unexpected, and, in all sincerity, he felt it was the crowning point of his career. He fully realised that in honouring him the Society was honouring his country. In his modest person they had celebrated very nobly and delicately the everlasting alliance between Great Britain and France. He also realised that it was an honour to his colleagues of the *Société de Chimie Industrielle*. It was especially gratifying to him that the medal should be handed to him by his old friend, Prof. Louis. He was a distinguished Past-president of the Society, and under him the Society had achieved some very great work during the war. He would say to Prof. Louis: "*Vous avez bien mérité de la Société.*" He concluded by again thanking them for the honour they had done him and, through him, the *Société de Chimie Industrielle*.

NEXT PLACE OF MEETING.

THE CHAIRMAN read to the meeting the invitation received from the Canadian section to hold the next annual meeting in Montreal. He formally moved the acceptance of the invitation.

MR. H. M. RIDGE seconded, and referred to the very great field which Canada provided for the work of the industrial chemist.

The invitation was accepted unanimously.

PRESIDENT'S ADDRESS.

PROF. LOUIS, in the absence of the President, read the Presidential Address. (This address will be published in full at a later date, when the President is able to complete and revise it.)

SIR WM. J. POPE said that they had met in the expectation of hearing a Presidential address which would summarise the ripe experience of one of the foremost and most successful of British chemical technologists; he ventured to think that their anticipations had not been disappointed. The address would be read with keen appreciation and would furnish material for serious thought to all interested in the aims and objects of the Society of Chemical Industry. The subject of chemical technology now loomed much larger in the public eye than had been the case six or seven years ago, and for a two-fold reason. In the first place, the war had taught the whole thinking portion of the world that the possession of an effective chemical industry was absolutely vital to the continued existence of any modern nation; secondly, the magnificent results achieved by British technical chemists during the war had taught the whole world that this country was easily capable of developing chemical manufacture in such a manner as to render the Empire entirely independent of foreign production. The vast British output of chemical products, many of which had been never before manufactured in this country, which had been worked up between 1914 and 1918, had resulted from the labours of men like their President, of men who, from the exacting nature of their occupations, had come but little into the public view.

Whilst proposing a vote of thanks to the President for his address he was sure they would wish him to express the sorrow of all present at the reason for Mr. Gray's absence; their President was now paying the penalty of overwork undertaken in the national service. He had written to him (Sir William) expressing regret at his inability to attend the annual meeting, and his absence to-day was causing him the most bitter disappointment.

They were fortunate in having been able to entrust the delivery of the Presidential address and the conduct of the annual meeting to one who was a veteran in the service of the Society. Professor Henry Louis was always ready to step into a breach and to give them the benefit of his wide experience and of his well-known businesslike mode of conducting affairs.

He desired to propose that a very hearty vote of thanks be passed to their President for his address, that they should express their sympathy with him in his illness and their hopes for his speedy recovery, and that they should thank their acting President, Professor Louis, for the manner in which he had presented the Presidential Address.

MR. WALTER REID seconded the votes of thanks, which were carried with acclamation.

THE CHAIRMAN thanked the meeting, saying it had been a pleasure to discharge the duties and that he was always ready to do his best for the Society.

MR. L. G. RADCLIFFE moved, and MR. JULIAN L. BAKER seconded the re-election of the auditors, Messrs. Price, Waterhouse and Co. This was agreed to.

At the close of the meeting the Chairman announced that the Scrutineers reported that the following were elected to the Council as the result of the ballot:—*President*: Sir William Pope. *Vice-Presidents*: Mr. John Gray, Mr. D. Lloyd Howard, Dr. S. Miall, and Mr. E. Thompson. *Ordinary Members of Council*: Dr. T. H. Butler, Mr. W. H. Coleman, Mr. F. H. Carr, and Dr. F. C. Garrett.

CONFERENCE ON BY-PRODUCT COKING.

On Tuesday afternoon a conference on by-product coking was held in the Chemical Lecture Theatre, Armstrong College. Prof. P. Phillips Bedson, in the chair.

THE CHAIRMAN said that it was impossible to over-exaggerate the importance of the complete utilisation of coal—a subject which, during the past few years, had been brought home by the increased cost of coal, but it was a matter for regret that it had taken us so long to appreciate and make headway in the practice of coking coal, especially as regards the recovery of by-products. Of the factors which had contributed to the backward condition of the British by-product coking industry the first was that in this country, and particularly in Durham, such a good supply of excellent coking coal was available. The second factor had been that in making iron it had been found that a slightly larger amount of retort oven coke was needed than of beehive coke, and that undoubted experimental fact, supported by the dictum of Sir Lothian Bell, had deterred many from embarking on the recovery of by-products when coking coal.

BY-PRODUCTS FROM COKE-OVENS.

BY E. W. SMITH.

The supply of by-products from coke-ovens has now assumed a position of great national importance, and much more remains to be done before the commercial and financial possibilities of by-product coking can be said to have reached their limit.

In beehive practice—which still persists in some

districts—not only were all the valuable by-products lost, but also the gas and a part of the top layers of coke amounting to about 10 per cent. The beehive oven will completely disappear when the methods adopted in by-product practice are such as to provide a coke having the necessary physical characteristics of beehive coke for the particular industrial requirements and when some of the users of beehive coke realise that not all the characteristics of this coke are essential to their particular operation. Much uncalled-for prejudice exists amongst furnacemen in favour of the beehive coke; by-product coke can be made which, when properly used, will give equal results with beehive coke.

The following are authentic figures prepared by the National Benzol Association from official returns:—

Statistics of coke oven plants for 1918.

Tons of coal carbonised	14,635,403.
Galls. crude 65s benzol produced	32,162,598.
Galls. crude 65s benzol per ton coal (average)	2.18
Tons of coke produced	10,552,648.
Galls. of tar produced	102,781,090.
Galls. per ton of coal (average)	7.0
Tons sulphate of ammonia produced	134,357.
Tons concentrated ammonia (25%) produced	23,899.
Pounds of 25% ammonia, total per ton, calculated from above two figures	24 0

The actual number of by-product ovens in use may be seen from the following figures:—1914, 5893; 1915, 6491; 1916, 7719; 1917, 8219; 1918, 8412; and over 1000 further ovens were under construction during 1919.

From the above figures it would appear that even after taking into consideration the necessarily different conditions between coking and gas-making practices the yields of tar, benzol, and ammonia are low.

In by-product coking, gas is the chief by-product. In all cases about 60% of the stripped gas is used for heating the ovens, and the residual gas is used for steam raising and other heating operations on the works. Because this gas is looked on as "surplus" gas, very little attention is paid to the question of the efficiency of its use on the works.

The present methods of steam raising at coke ovens—with gas in Lancashire boilers—are not only in most cases wasteful because the gas might be put to more profitable use and the steam be raised by cheaper means, but in most cases the gas is inefficiently applied for steam raising. It is only where there is no other possible outlet that it is justifiable to use it for steam raising, and even though there be an ample supply of surplus gas for the whole needs of the works it will still pay to obtain a higher efficiency from the boilers.

Every conceivable opportunity should be seized for supplying coke-oven gas to gas undertakings that are requiring extensions. The gas is practically identical with that produced in horizontal retorts on gas works, and there are no "snags," as has been proved during the last eight years at the Saltley Gasworks, Birmingham, where there is an installation of 66 regenerative ovens taking a charge of between 9 and 10 tons of coal per oven. The yields of tar, ammonia, and benzol are quite up to the average of the horizontal retort results. Coke-ovens have this surplus gas, and it only requires freeing from hydrogen sulphide to make it fit for use in towns supply. If coke oven proprietors desire to sell their gas as a by-product for towns supply it will be necessary to study the subject from the consumer's point of view, as the operation is not one merely of piping the surplus to the inlet of the gas undertaking's purifiers.

The conditions of sale of gas for towns supply have radically changed during the last few years, and now that gas is to be sold on the basis of thermal units and not by cubic feet there is not quite the same latitude that there has been unless

a substantial B.Th.U. "overweight" be maintained. By means of recorders, official State Gas Examiners will test the towns supply and have records of the quality of the gas for every hour of the day. Consequently, as it is not possible to keep an absolutely constant quality, gas undertakings will have to work for a gas consistently above the declared standard, and as the charges are based on the multiple of cubic feet and declared calorific value all in excess is "overweight."

One of the difficulties coke ovens will have to contend with is the question of inerts—nitrogen and carbon dioxide. Although the Research Committee of the Leeds University and the Institution of Gas Engineers have shown, after exhaustive experimental work, that similar efficiencies are obtainable from gases varying widely in their inert constituents, no gas apparatus can adjust itself for changes in quality. The question of inerts is not, therefore, one of thermal efficiency, but one of density. A straight coke-oven gas stripped of benzol and containing no more nitrogen than that which came from the coal would have a density between 0.42 and 0.45. With about 10% nitrogen it would be between 0.48 and 0.51, and with 20%, 0.51—0.59. Not only does the calorific value usually vary correspondingly, but, with the same pressure, actually a smaller volume of gas can be consumed in the apparatus when the density of the gas increases.

The ideal to be aimed at is to produce and deliver to the consumer's premises a gas under as nearly as possible constant conditions, and the only factors of material moment are calorific value, density, and pressure.

Gas high in inerts, though no inconvenience to the consumer when paid for on a heat-unit basis, is a nuisance when the percentage of inerts varies considerably. It is also more costly to distribute and purify, and pressure changes in the distributing system are much more frequent.

In straight carbonisation practice such as that in horizontal retorts, B.Th.U.s. are dearer when associated with 30% of inerts than when associated with 15% of inerts—it being assumed that the ovens and retorts are in a reasonable state of repair and that the inerts come from the retort house.

Inerts in coke-oven gas are usually higher than in towns gas. This is due to the retorts being tighter than ovens and to better means being adopted on gasworks for controlling the pressure of gas as it leaves the retorts than is maintained at the offtake of the ovens. This is a matter that can be remedied.

Lastly, on this question of gas as a by-product, I am convinced that when large extensions of ovens are contemplated and where there is an outlet for the gas produced for boosting up the towns supply, the question of heating ovens by means of externally produced by-product recovery producer-gas should be fully considered, with a view to releasing for towns use not 40% of the make of gas, but the whole of it.

In the subsequent treatment of the crude gas entering the foul main the methods adopted on coke-ovens and in gasworks vary very considerably. On coke ovens the aim is to extract efficiently tar, ammonia, and benzol. On gasworks, tar, sometimes cyanogen, ammonia, occasionally benzol, and always hydrogen sulphide. Tar is eliminated by condensation and "frictional" devices, and usually finally by strong liquor washing.

Pitching troubles are usual on coke ovens and in gas works practice where the carbonising chambers or offtakes are leaky and the gas entering the collecting main is overheated. Short offtake pipes are also frequent causes of pitching troubles, and high ammonium chloride content of hot foul gas aggravates them. The circumstances of each case have to be studied separately, as there is no panacea

for the cure of pitching or emulsions. Not only are the troubles costly to handle, but the tar produced would, in normal times, be of much less value.

Tars from coke ovens are dealt with in a very similar way to those from gasworks. It would appear, however, that the temperatures attained during carbonisation are lower in coke ovens than on gasworks, although the long soaking heats usual in a coke oven make up for this difference somewhat. I believe it would prove of financial advantage to run many installations at higher temperatures in the combustion chambers—to 1300° C. Much lower temperatures than these are normal. There would be a greater throughput, a better gas, and better by-products.

I am still to be convinced that stamped charges containing 15–20% of water are so frequently necessary. They certainly do not improve the by-products, and are in many cases of doubtful necessity from the point of view of the coke.

Sulphate of ammonia.

Although it is the usual practice to produce sulphate of ammonia on coke ovens, in many cases it would be more profitable to make pure concentrated ammonia liquor. It is an open question whether it would pay, however, at the present time to scrap plants which were installed when capital costs were low and replace with plants at such high capital costs as are ruling at the present time. In the case of completely new installations this matter should be given very full consideration.

It is usual to maintain the gas entering the saturator at a temperature of at least 67° C., and the liquor in the saturator is still further heated by means of steam-heated lead coils. The heat of reaction inside the saturator also helps to maintain the temperature, and in this way a highly concentrated hot sludge is made, which, when released, drained, washed, and centrifuged, leaves a salt containing from 24% to 25% NH_3 , about 0.1% of acid and up to 2% of water. If this country is desirous of retaining the foreign markets wrested from Germany during the war greater care will have to be exercised by most makers of sulphate in the production of a dry, neutral salt. Higher prices are obtainable for such a product which cover the extra expense entailed.

In gasworks' practice it is usual to extract the hydrogen sulphide present in the crude gas. The manufacturing cost of this purification in the usual oxide purifiers is about 0.1d. per 100 cb. ft., after taking credit for the sulphur in the spent oxide. The sulphur recovered is more than sufficient for the whole production of ammonium sulphate.

On coke-ovens this sulphur is not recovered, but if the whole of the gas produced was used for towns supply the sulphur would have to be eliminated and would be available for acid production.

The present capital cost of oxide purifiers, including everything, is about £20,000 per million cb. ft. of gas made per day, so that there is ample room for new methods that can displace those ruling at present at a lower capital cost. Much work is being done on the subject both here and in America, and it would appear that a big advance will be forthcoming.

In some oven installations ammonium chloride is being successfully extracted from the hot gas before the free ammonia comes down. This is usually carried out at the tar extractors, and not only is there an enhanced financial gain but the tars are as a result comparatively free from chloride and the tar stills have a correspondingly increased life.

It would appear that the amount of ammonia recovered in coke-ovens is not so high as in gasworks from similar coals. This may be due to a number of causes—most of which are controllable. It is beyond the scope of this paper to go into this question more than to mention it.

Benzol.

During the war, gasworks starting *de novo* had opportunities of studying the question of benzol extraction which had not been available to coke-oven managers. Rhead's paper on the working of the benzol plant in Birmingham added much to our knowledge on this subject.

The quantity of benzol recovered depends (1) on the quantity produced in the ovens, (2) on the quantity destroyed either in the ovens or the offtake pipes, and (3) on the efficiency of extraction from the gas in the scrubbers. Higher temperatures of carbonisation will improve the first. Leakage in the ovens is largely the cause of the second, and high temperature of wash oil and unsuitable oil are largely the causes of low efficiency of extraction.

While coke-ovens are, in the main, not selling their gas for towns supply, the extraction of benzol makes very little difference to the financial value of the gas. In gasworks practice the stripped gas is equally as good as unstripped gas for towns supply, but the number of B.Th.U. sold per ton of coal is less when benzol is extracted than when the gas is sold unwashed. The calorific value is reduced about 13 B.Th.U. per cb. ft. per gallon on a gas of 530 B.Th.U. gross. The loss is worse than it seems where water-gas is used to any extent and the standard of quality to be maintained is normal. The value of the B.Th.U. is not necessarily that of the coal gas B.Th.U., but may conceivably be that of the alternative enrichment. Consequently gasworks at the present time must charge against the cost of extraction of benzol the value of the gross B.Th.U. to the gas undertaking as gaseous B.Th.U. This aspect of the question need never be taken into account on coke ovens as the gas is a by-product.

If it were not for the fact that gas undertakings must eliminate naphthalene from the gas distributed, it is doubtful whether it pays them to wash for benzol at the present time, but the circumstances of each particular undertaking must be taken into account before any conclusion can be arrived at.

Alcohol and cyanide as by-products are new to coke-oven practice. It must suffice to say here that as regards alcohol, the process being developed by Mr. Ernest Bury shows great promise, but there appear to be difficulties in connexion with the loss of acid and quality of fuel that have still to be surmounted. As regards cyanogen—where temperatures are maintained reasonably high in normal times its extraction would be profitable, but present capital costs of plant make them prohibitive.

Discussion.

Mr. H. E. WRIGHT said that Dr. Smith had spoken of 40% surplus gas in the coke-ovens. In the newer regenerative types it was more like 50–55%, and in the waste heat type 25–28%, depending on the quality of the coal used.

Mr. A. E. F. KNOTT said that he thought the losses in the by-product oven as compared with the beehive oven were nearer 5% than 10%. The coking temperatures given by Dr. Smith appeared more like the American practice. No doubt there were many good features in that method, but he did not think such temperatures could be adopted in England without rebuilding with a class of silica bricks which would withstand temperatures higher than any obtainable in England.

Mr. E. E. WOOD said that at the works at which he was engaged they had found that any coke which could be used in the ordinary cupola was suitable for the blast furnace; it was more difficult to get a good cupola coke from patent ovens than a good blast-furnace coke. Better coke was obtained by coking at lower temperatures and for longer periods.

Mr. S. A. WICKNER considered that more attention should be paid to keeping ammonium chloride

out of tar. When present it was difficult to remove and became a great nuisance.

Mr. W. DIAMOND said that there were burners now on the market which would burn coke-oven gas quite efficiently under boilers.

Dr. SMITH, in reply, said that the figure of 40% for surplus gas that he had given was in connexion with the average oven. Regarding the use of high temperatures in ovens, he said that at Saltley Gasworks, Birmingham, the ovens were kept at the high temperatures he had named; there was not much fear of the cracking of the hydrocarbons passing through the heated chamber at the top of the oven. At low temperatures benzol was not produced in such quantities as at high temperatures; the amount produced compared very favourably with the best horizontal retort practice. That indicated that high temperatures were not a deterrent. They used English bricks—he believed Leeds silica bricks—and the life of the ovens was quite satisfactory. In his opinion, if 1s. 6d. could be obtained for coke-oven gas for town supply it was wasteful to use it on boilers.

THE CORROSION OF COKE-OVEN WALLS.

By W. J. REES, F.I.C.

Lecturer in Refractories, University of Sheffield.

In some of the coke-producing areas (for example, South Yorkshire and North Derbyshire) the corrosion of coke-oven walls due to the presence of salt in the coal is a serious factor in its effect on the life of the oven. In the Sheffield district, when deep coals are coked, this corrosion is very severe. In a particular case where coals from the following seams were being coked:—The High Hazels seam, at a depth of 120–130 yds.; the Barnsley seam, at 216–316 yds.; the Parkgate seam, at 460–560 yds., and the Silkstone seam, at 540–640 yds., extraction by water showed 0.37% of NaCl and 0.19% of Na_2SO_4 in the unwashed slack and 0.18% of NaCl and 0.08% Na_2SO_4 in the washed slack as delivered to the ovens. With continued extraction with hot 10% nitric acid, further quantities of both chloride and sulphate were removed from the slack, in several cases nearly 1% of NaCl being extracted. The pit waters frequently used in the washery contain large quantities of dissolved salts, as shown in the following table:—

	Pit water from pumping station	Water in circulation in washery	Drainage water from washed slack hoppers.
	Grams per litre.		
NaCl	0.451	1.529	1.944
Na_2SO_4	0.149	0.521	0.768
K_2SO_4	0.052	0.062	0.072
CaSO_4	0.243	0.168	0.165
MgSO_4	0.357	0.264	0.261
CaCO_3	0.095	0.057	0.062
MgCO_3	0.051	0.041	0.023

and the question arose as to whether the use of a pure water, such as that of a town supply, would be advantageous. Laboratory experiments showed that there was little or no gain in either the rate of extraction or salt extracted by the substitution of either distilled or town's water for the impure pit water. The use of a purer water would, of course, result in some diminution in the quantity of dissolved salts sent to the oven in the water adhering to the slack, but the expenditure involved would not be justified by the comparatively small reduction obtained. The rate of flow of water through the washery is a point which may be worth consideration where very salty coals are being washed, as with an increase in the rate of flow there will be a reduction in the concentration due to the solution of salts from the coal and a corresponding reduction

in the salt content of the water adhering to the slack. In some pit and hopper drainage waters considerable quantities of magnesium chloride have been found and, in view of its ready hydrolysis, this may have an important effect on the coke-oven walls.

Taking the figures given above, there will be carried into the oven with each charge of slack and adhering water approximately 50 lb. of NaCl and 20 lb. of Na_2SO_4 . The salt present will begin to volatilise at 800° C. (to a small extent at lower temperatures, as salt has an appreciable vapour pressure at temperatures below its melting point) and in addition to this removal of salt by volatilisation there will be some removed by hydrolysis as steam from the centre of the charge comes in contact with the hot coal. The sodium sulphate present will also probably have some activity as a corrodant, as by interaction with the coal at the temperature of coking, sodium carbonate will be formed. H. V. Thompson,* in discussing the dissociation of salt, has shown that when a current of dry air is passed over molten salt at 1100° C., the salt vapour carried forward by the air was 0.0554 g. per litre. With a current of moist air, the salt carried over was increased to 0.0782 g. per l. The coking of wet slacks may thus be a factor of importance in cases of oven-corrosion. The moist air with the salt vapour and the products of hydrolysis was then passed over (a) quartz chippings, (b) ferric oxide, (c) alumina, (d) clay. With the quartz there was a superficial attack only, a little sodium silicate being formed; with the ferric oxide, a little ferric chloride was formed, and there was, incidentally, a conversion of the bulk of the Fe_2O_3 into black crystals of Fe_3O_4 ; with the alumina, the attack was even less than on the quartz, a little sodium aluminate being formed. In the case of the clay, however, severe corrosion was observed, increasing with the iron content of the clay. In a paper recently communicated to the Refractories Section of the Ceramic Society† I have described a series of experiments in which the action of salt vapour (at 800°–950° C.) on silica, silicious fireclay, semi-silica and fireclay bricks was observed. The attack was, in general, much greater on the fireclay than on the other bricks.

The action of salt on clay has been extensively studied in connexion with the phenomena of salt glazing, and this directs attention to an important difference between the conditions of salt-glazing and the conditions which result in the corrosion of fire-clay coke-oven bricks. In salt-glazing, the kiln atmosphere will be much richer in salt vapour than a coke-oven at any period, but the salt is not applied until the articles to be glazed are at a temperature of about 1200° C. At this temperature the salt immediately combines with the clay, forming a glass which coats the exposed surface of clay and protects it from any further attack by the salt vapour. The important factor in salt glazing is that the articles to be glazed shall be at the temperature at which interaction between salt and clay is rapid. In the coke-oven the conditions are essentially different, the internal wall of the oven never reaching the temperature at which salt glazing is rapid. J. W. Cobb‡ has shown that interaction between sodium carbonate, alumina, and silica will take place at temperatures much below that of fusion of the mixtures, and it is evident that this type of reaction is important in coke-oven corrosion. In the coke-oven, the salt vapour instead of reacting with the surface of the bricks will penetrate them; there may be some deposition of salt inside the brick, but a good deal of the vapour apparently passes on until it reaches a zone in the brickwork at which the temperature is high enough for interaction to take

* Trans. Ceramic Society, 1918; see J., 1918, 333 A.

† Spring Meeting, 1920.

‡ J., 1910, 69, 250, 335, 399, 603, 799.

place with some rapidity. The joint result of the slower interaction in the cooler portion of the brick and the more rapid action in the hotter zones is the formation of a weak, spongy mass which becomes increasingly open to the attack of the salt and which may fall away or be dragged away by the moving coal or coke. Another important phenomenon in connexion with this corrosion is the very general presence of a layer of hæmatite in that portion of the brick where disintegration and shearing take place. This appears to be due to the formation and volatilisation of ferric chloride by the action of salt vapour on iron oxide present either in the coal or more probably in the bricks. The ferric chloride vapour penetrates the porous bricks until it reaches a zone to which oxygen-containing gases from the combustion flues penetrate, and it is there oxidised with the formation and deposition of hæmatite. In this way layer upon layer of hæmatite may deposit until it reaches the thickness which may frequently be observed in old corroded bricks. The formation of ammonium chloride (and possibly also the presence of free chlorine) may also be a factor in corrosion; the passage of ammonium chloride vapour over fireclay bricks at coking temperature shows only very slight indications of corrosion of the brick, but that continued action may result in the formation of ammonium or ammonia-alumino-silicates is evident from the action of ammonium chloride in the Lawrence Smith method for the determination of alkalis in silicates. Attempts have been made to prevent the penetration of vapours or increase the resistance to corrosion by facing or glazing the surface of the bricks, but up to the present these have been unsuccessful, the face falling away owing to the difference in the coefficient of expansion of brick and face.

The question now arises as to which is the best type of brick to use for coke-oven walls. When the coals to be coked contain little or no salt, it is probable that a good, well-burned fireclay or fireclay with silica grog (semi-silica) brick will be satisfactory, but in the case of salty coals the experimental evidence indicates that corrosion is likely to be much more severe on fireclay than on silica, alumina, or magnesite bricks. With an alumina brick the physical changes will, during use, be in the direction of continuous contraction, and, unless an electric furnace product such as alundum is used this type of brick is therefore ruled out. There is at present no quantitative evidence which indicates whether or not the high initial cost of alundum or magnesite bricks would be counterbalanced by the increased life of the oven. The physical changes in a silica brick during use are rather complex, the most important of them being the growth due to the gradual transformation to tridymite of the quartz in the brick. But if, in burning the brick, a maximum conversion of the quartz to the form of lower specific gravity is obtained, it is evident that the increase in volume of the brick during its subsequent use can only be small. Further, if by special grading of the raw materials and the formation of a suitable matrix, the recrystallisation of the silica takes place so that the newly-formed crystals tend to interlace instead of to push against each other, the mechanical strength of the brick will be increased and its porosity reduced. The characteristics of the ordinary type of silica brick which render it unreliable for coke-oven use are its continued growth during use, its rather high porosity and its tendency to spall from the repeated changes in temperature; but it is now possible, by combining the two factors of suitable grading and adequate burning, to produce a silica brick with physical properties such as should make its successful use in coke oven practice a distinct probability. Such bricks are already being made and put into use in situations where corrosion trouble has been severe.

A factor which will be common to all coke-oven bricks in its influence on disintegration is that due to the deposition, in the pores of the brick, of carbon from the decomposition of hydrocarbons in the coke-oven gas or from the gases in the combustion flues. The reduction to the ferrous state of any iron oxide present and the possible formation of easily fusible ferrous silicate will also be a factor in the behaviour and life of the brick.

The heat conductivity of the brick used for the coke-oven needs some consideration. This is so much affected by factors such as the temperature of burning, porosity, etc., that no figure short of that obtained by actual determination on a particular brick is of any great value. Experience in American coke-oven practice indicates that at coking temperatures the conductivity of a good silica brick is decidedly greater than that of a fireclay or semi-silica brick. This should be a further point in favour of the use of silica bricks in coke-oven construction.

MODERN BY-PRODUCT COKE-OVEN CONSTRUCTION.

BY W. A. WARD.

In Great Britain even yet an inordinate amount of our metallurgical coke is produced in beehive ovens, although it is well known that the yield of coke from by-product ovens is much higher and the quality of the coke quite as good. This is due to the prejudice of iron manufacturers in favour of the larger coke generally yielded by beehive ovens and its appearance, and also to the higher capital cost of a by-product coking plant and the greater importance of continuous working.

It is, however, possible to approach nearer to the theoretical calorific intensity of combustion with smaller coke and thus make the most economical use of it because it will lie closer in the furnace and render possible a reduction of the amount of excess air passing through.

It must, nevertheless, be admitted that some of the by-product coke made in years past was very poor. It was uneven in quality and structure, soft, and contained too much volatile matter and moisture. These defects were in part due to the ovens, low uneven heats, leakage, and careless quenching. Quite as certainly, however, they were due to the use of unsuitable or badly prepared coal.

The suggestion is frequently made that we in Great Britain should pool our resources in the matter of coal supply and manufacture coke, by-products, and gas on a large scale in joint works. It would have enormous advantages in the mixing of coals, continuous operation at full load, reduction of working costs, products of uniform quality, and higher all-round efficiency.

The choice of site for a coking plant is a matter requiring very careful study. The first essential is the traffic in connexion with the plant and its incorporation as an integral part of the general traffic scheme of the works. Where no really suitable place from the traffic standpoint can be found on the pillar where there will be freedom from sinking due to mining operations, as also when no alternative site of any kind is available, resort must be made to the use of aerial ropeways, overhead conveyors, large ovens, and the recent developments in coke handling plant described later.

Future extension should always be considered and provided for when laying out the original scheme. Use should be made also of any natural advantages of position such as ground rising from the coke side which will cheapen the discharging machine terrace whilst not seriously interfering with the by-product roads behind.

Type of oven.

The choice of a type of coke-oven to be used at a by-product plant will be decided by the manner in which the surplus heat available is to be made use of, and no other consideration really need be taken into account.

It is often stated that regenerative ovens are more efficient than non-regenerative, because through regeneration a larger yield of surplus gas is available. *Ipsa facto* this is somewhat erroneous. There have been cases of such a difference, but they are due to defects in design or construction or else to faulty operation. The surplus energy is the same, because the amount of heat necessary to coke the coal is the same, whatever the type of oven, unless its form be such as to increase losses by radiation etc., or the arrangements for combustion of the heating gas are faulty. The difference lies simply in the manner in which the surplus heat is made use of. By the provision of adequate heating surface and equal care in general design and insulation, the gases entering the stack may be at exactly the same temperature in either. In fact, generally there will be more excess air in regenerative oven flue gases which will carry a lot of heat to waste.

This being so, the difference in power available for use outside the plant and after all its demands have been met as between the two types, is simply the fundamental one as between the efficiency of the gas engine and the steam plant. It is impossible in practice to attain the same efficiency with the steam raising plant, but this is not the fault of the type of oven. Furthermore, steam is necessary on every complete plant whatever the main source of power, and this must be taken into account when drawing up a complete energy diagram.

Generally speaking no attempt is made on coking plants to make full use of the hot waste gases from the ovens, whether these be regenerative or non-regenerative. It is quite common to find gases entering the chimney at 310° C. from regenerative ovens and 460° C. from waste heat ovens and neither steam superheaters nor economisers in use; 250°—280° is sufficient if the chimney and flues are correctly designed. Again gas will often be burnt for the purpose of drying, subliming, evaporating, etc., while these "waste" gases are doing nothing. Of course, they cannot be used any further for direct steam raising in the boilers, but the obvious solution is to use them for superheating the steam and raising the temperature of feed water etc., extensions of the total heating surface which are common in almost all other industries and which are suitable for the low temperature differences. They might also be used for superheating exhaust steam, from back pressure turbines, or ordinary reciprocating engines which could then be used in the by-product plant or for reheating gases etc.

Superheated steam should be more generally used on coking plants not only for power purposes, but in ordinary process work where it is most important that the steam should arrive at apparatus as steam with some latent heat to give up, and not merely as hot water.

An extension of heating surface outside the non-regenerative or non-recuperative oven would make it approach nearer to the heating surface of the regenerative oven, which came into being through this necessity for heating surface suitable for abstracting heat from the tail-gases.

Another very important point on this question of heating surface is that presented in the oven wall and the application of heat to it. This will be referred to later.

The non-regenerative or waste heat oven cannot be economically used unless there is a continuous and regular demand for steam, and the boilers can be placed close to the battery of ovens.

In the case of intermittent loads or wide fluctuation, regenerative ovens should be chosen

whether power is generated direct in gas engines or by steam, because the surplus gas can be transmitted almost any distance and stored in a gas-holder until required. This applies also when the steam raising plant is remote from the ovens.

Many waste heat ovens are arranged on the recuperative principle. That is to say an attempt is made to recover heat which would otherwise be lost by radiation from the brickwork of the oven foundations into the atmosphere, or by conduction into the ground. At the same time the current of air for combustion of the gas by which it is done serves to keep the galleries in which the gasmen have to work in a moderately cool and comfortable state. Generally recuperation is carried no further than this at the present day, although in the past, as in the old Simon-Carves oven, special flues were constructed for the purpose.

A novel form of producer-gas-fired oven with continuous recuperation for both gas and air has recently been introduced by Messrs. Simon Carves, Limited, and a small trial battery erected at Cargo Fleet Ironworks, nr. Middlesbrough. I am not able to give details at present, but the principle has been carried much further than ever before.

The producer- or blast-furnace-gas-fired oven of regenerative type, both simple and compound, for the use of poor or rich gas or both, is an accomplished fact.

There is no fundamental reason for any great difference in results to be obtained from the various types of oven, and it is undoubtedly true that very good results are regularly obtained from all types. The best are frequently obtained from ovens which would appear of inferior design. This, however, is to the credit of the working staff. A good feature in one type will often be counter-balanced by one of a different kind in another type not containing the first. For instance, distribution of heat may be more even and easier to maintain in that state in a particular type of regenerative oven than, say, in a waste heat oven with horizontal flues, owing to the greater volume of hot gases and air at the point where distribution to the walls takes place. This may be balanced by the fact that there is a larger mass of hot brickwork in the horizontal flue oven walls to act with a fly-wheel effect, also that the gas tuyères are more accessible and of better type permitting of a more thorough primary mixture of gas and air and a nicer regulation of the amount of excess air.

Description of various types of oven.

The Coppée waste heat oven (fig. 1) is of the vertical flue type having dual waste gas flues. Each half of each oven wall is entirely separate from the other with regard to gas and air supply and regulation and served by one of the aforementioned waste gas flues. This arrangement is excellent as tending towards even distribution of heat, even expansion of the battery and distribution of weight on the ground, and permitting very good recuperation by the air for combustion and insulation of the foundations at the same time. It is heated by rich gas brought along each side of the battery in mains, A, from which separate branch pipes, B, lead to gas conduits, E, under the centre of each oven wall. Before reaching there the gas passes through mixing boxes, D, designed on the Bunsen burner principle, and primary air is thoroughly mixed with it. These mixing boxes are each capable of regulation by the gas man as he watches ignition through a convenient sight-hole in the gas tuyère. Secondary air for combustion of the gas enters the flues or conduits, H, at each end of the battery and passes into distributing flues, J, from which small conduits, K, lead to each oven. These conduits each feed three air-distributing canals communicating with three groups of vertical flues, making six

groups per wall. Dampers are provided in each canal for regulation.

Each waste gas flue is completely surrounded with air ducts, so that full advantage is taken of the heat otherwise lost from the substructure.

Fig. 2 shows by vertical sections the design and arrangement of the Coppée regenerative oven. It is of the vertical flue type, and is built on similar

duits lead to each oven. This arrangement permits of a solid construction of practically the same class of material throughout, and as the whole of the substructure is kept at approximately the same temperature there is no unequal expansion with its consequent distortion and cracking etc. The air is drawn by means of a fan through galleries and ducts under the regenerators and collecting

lines to the waste heat oven except that the air for combustion of the gas is heated in the regenerators to an intense degree, viz., over 1000°C .

Unlike most other types, the air passes through the whole length of the regenerator and then into collecting flues, from which the distributing con-

duits lead to each oven. This arrangement permits of a solid construction of practically the same class of material throughout, and as the whole of the substructure is kept at approximately the same temperature there is no unequal expansion with its consequent distortion and cracking etc. The air is drawn by means of a fan through galleries and ducts under the regenerators and collecting

flues, so receiving a preliminary heating and serving to keep the foundations and ground reasonably cool.

The weight of the oven structure and mountings, also of the coal in the ovens, is distributed on arches and piers running at right angles to them;

this feature, which is shared by other designs of oven such as the Simon-Carves, is the most correct from an engineering standpoint.

The 30 vertical flues in the oven wall are divided into five groups. The six flues of each group are divided into two groups of three, each being used alternately for ascending and descending gases by simple reversal of the damper.

There are two gas tuyères on each side of the oven with cocks for reversing, in addition to valves for regulating and shutting off the supply. The reversing cocks are all operated simultaneously by levers and a wire rope when the main damper is reversed.

The distribution of the 15 flues in which gas is burning, throughout the entire length of each wall, and the alternation of these in adjacent walls, effect a very even distribution of the heat; this is an improvement on the systems in which the whole of the flues in one half the oven are used for ascending gas and all those in the other half are used for descending burnt gas. There is also less tendency to overheating at the top due to the passage of very large volumes of hot gases through a more or less restricted space. This is of advantage in preventing the decomposition or degradation of by-products. The same effect is obtained in this and other ovens by keeping the top flue some distance below the crown of the oven.

The ovens in a battery like this are not independent either in air supply, regenerators, or combustion of the gases.

Another type is built with separate regenerators for each oven arranged under the oven chamber and athwart the battery. This is a later development, and is common to most firms of coke-oven engineers. The advantages claimed are, a greater regenerator capacity in the same space or equal capacity in less, complete independence of each oven so that the others are not affected if some are off for repairs, or "sick" for any reason, better facilities for examination and repairs to regenerators, better regulation of draught and air supply. The last-named is probably the greatest, because air supply and draught are regulated separately instead of relying on one damper setting more or less permanent to regulate draught and air successively on reversal as in the older types.

All the advantages do not rest with the newer type, however. Stability has had to be sacrificed to a certain extent, and much greater care has to be exercised in connexion with longitudinal expansion of the battery. Giving to each oven a separate existence precludes help being given to a "sick" oven by the remainder. Further, the very facilities for independent adjustment and the more accurate regulation and distribution of heat, which make a larger output and better general quality of both coke and by-products possible, are in themselves a danger if neglected or left in the hands of men not properly instructed or in any way uncertain of the results likely to follow changes they make in regulation.

In connexion with the problem of stability, I would draw attention to the five longitudinal walls in the Coppée ovens of this type, the retention of the arches and piers in the oven designed by Messrs. Coke and Gas Ovens, Ltd., and also to the retention of a central flue or duct in the original Koppers oven. Provision is also being made for expansion and stability by shape, arrangement, and bond of blocks.

The Coppée independent regenerator oven is divided into four sections athwart the battery as regards arrangements for heating. Instead of one-half the flues in each wall being used for ascending hot gases in the initial stage of combustion and the other for descending gases as in other types, two alternate sections are used in each case. The

aim is a more even distribution of heat and a smaller area of the oven affected by changes due to reversing. Dampers control the inlet of air and exit of waste gas, and reversing is effected by cocks and dampers operated by wire ropes from a winch at the end of the battery. The gas supply is arranged in a similar way to that of their older oven previously described, except that there is of course no primary air admission.

These arrangements appear to make it possible to regulate the amount of gas burnt to compensate for the natural tendency towards a hot zone at the centre of the oven due to radiation losses from the ends, and also for the extra heat required to coke the greater thickness of coal at the discharge or coke bench side of the oven, or the greater density at the narrow end due to withdrawing of the peel in the case of an oven charged by coke.

The Coppée compound oven is modelled on similar lines save that each regenerator chamber is divided into two parts by additional walls running from side to side of the battery, thus providing regenerators for both producer- or blast-furnace-gas and air. It is necessary, owing to the low calorific value of these gases to raise their temperature to about 1000° C. before ignition.

The producer- or blast-furnace-gas is brought along each side of the battery in the regulating galleries, and specially designed connexions convey it to the inlets at the bottom of each regenerator. Reversing of gas and air is carried out by wire rope gear as previously described.

The distribution of gas and air to the vertical heating flues in the oven walls is effected by inclined ducts from a compound sole flue as before, and waste gases follow the same course in the reverse direction, thus heating up the chequer work before entering the waste gas flue, ready for the next reversal.

In addition to the arrangements for heating by means of poor gas, there are supply pipes and tuyères with reversing valves for rich gas, so that if for any reason a change becomes necessary, a few minutes is sufficient to convert the oven to the ordinary regenerative type using a portion of the gases evolved from its own charge. In this event a simple device enables the whole of the regenerators to be used for air in the usual way. Furthermore, a small amount of this rich gas can be used at any time along with poor gas if there should be a falling off in supply or value. It can also be used to stimulate a backward oven, and so enable the regular programme to be maintained.

There is no doubt that the compound oven is the oven of the future, whatever the design, because of the greater value of the rich gas set at liberty for other purposes such as lighting, power, steel manufacture, and chemical processes. With the poor gas oven the whole of the gas evolved from the charge is available after recovery of by-products for extraneous purposes, whereas from the ordinary regenerative oven only 45–55% is available for purposes outside its own demands. In the case of the non-regenerative or waste heat oven no more than 5–25% of "live" gas is available, according to the natural yield of the coal and the extent to which recuperation is carried. It is often assumed that the percentage of spare gas will be practically the same for all coals, but this is not so. The losses from ovens of the same design are approximately constant.

Coke breeze or "bad coal" can be used in the producers for the supply of gas for heating purposes, and I believe actual experience has shown that the objection at first raised to ovens of this type that thermally and economically there was no advantage is groundless. In fact the yield is found to be higher from ovens of this kind because the greater volume of the gas and air mixture per equal number of calories effects a better and more

even distribution of heat, and owing to the specific heat of the waste gases less heat is lost via the chimney. R. Biermann has shown that a reduction of 7% in coking time is effected.

If blast-furnace gas is used it must be cleaned thoroughly, so that the mains and valves will not become clogged with tar, or fine dust containing compounds which will act as fluxes, choke the regenerators or damage the oven brickwork. There is not the risk of naphthalene blockage or carbon deposits as with the use of coke-oven gas.

spyhole, giving an uninterrupted view of the bottoms of all vertical flues in each half of the wall.

The patent covered the control of each separate vertical flue with its gas jet from the outside, or any arrangement of them into groups. In practice groups were adopted as it was too costly to arrange for each flue separately, and a finer division with multiplication of controls was judged to be unnecessary. These groups were arranged so that the amount of gas burnt in each was proportional

Fig. 3.

The Simon-Carves vertical flue regenerative oven, shown by figs. 3, 4, and 5, on its introduction about 1906 showed a marked advance in the matter of general design, especially the arrangements for distribution of gas and air, regulation of draught, accessibility, and facilities for continuous inspection during use. Some improvements have since been made, but substantially the design is the same, and it still holds a very high place in the coking world, giving results which compare favourably with those of other designs possibly more attractive on paper.

The fundamental difference in design was that the controls were all brought to the front and back of the oven and arranged in galleries under the discharging machine track and the coke-bench. Previous to this it had been usual to regulate the admission of gas and air by means of dampers or adjustable blocks and nozzles situated at the base of each vertical flue from galleries under the battery, or by rods inserted through openings in the brickwork. In practice this was so difficult and often uncomfortable owing to the heat and cramped space that it was neglected or improperly carried out.

The new arrangement meant that the nicest regulation could be effected in a few minutes, while the result was watched through a convenient

to the demands in order to make up for radiation losses and difference in thickness or density of the charge. The draught in each of these groups of flues was separately regulated at the outlets of the several ducts in the sole flue with which they communicate on the outlet side.

Further improvements in this oven are the dividing off of each group of vertical flues at their base and the use of gas canals of large section each provided with a removable plug in the gas distributing box, 38, through which each section can be separately examined.

In addition, means have been adopted for checking and regulating the draught at the top of each vertical flue. The last named is almost universal now in vertical flue oven practice.

The oven structure is supported on five massive brick piers and four arches forming tunnels running the length of the battery and at right-angles to the oven walls, thus forming the stable construction referred to earlier.

The regenerators, 14 and 14a, are accommodated in the two outer tunnels and built so as to be free to expand within same. The air for combustion of the gas traverses the two inner tunnels and enters the canals under each regenerator in turn, traversing freely from end to end and up through the deep mass of chequer work to each oven inlet,

15 and 15a, the correct amount being regulated by the setting of dampers, 59. There is no travel of either air or waste gas along the regenerator, itself, and therefore the heating surface is exactly the same for each oven and the friction uniform. No fan is used at these ovens, the chimney giving all draught required. Reversal of air and waste gas is by vertical dampers operated by a winch which simultaneously reverses all the gas tuyères.

From the air inlet, 15, compartments, 20 to 24 (fig. 4), are supplied through ducts, 17, 18, 29, and 30, which communicate with the bases of the vertical flues, 12, through inclined passages shown in transverse section in fig. 5. These it enters immediately above the gas and starts combustion about the sole level of the oven. The ducts, 61, 62, and 63, are for use when starting the ovens from fires in the oven chambers at each end, with which they communicate through openings in the sides of the charging holes. These openings are sealed with fireclay blocks when the oven is heated up and ready for normal work.

The Simon-Carves vertical flue non-regenerative

The oven is partly recuperative, the air being led through the two central galleries and over the tops of the waste gas flues to the distributing channels at the front and back of the oven where regulation is effected.

The well-known Simon-Carves horizontal flue waste heat oven is non-recuperative, and is arranged with one waste gas flue at the coke ram side of the battery. Its construction is very strong, the ovens being separated by a solid firebrick wall, usually 14 in. thick, which carries the superstructure, gas collecting main, charging car, etc., thus relieving the oven linings of any of this weight. The linings are tied into these central walls between each horizontal flue, the whole being made of tongued and grooved bricks so that an exceedingly strong and rigid structure not liable to distortion or leakage is the result. The ends of the walls at both ram and bench side are protected and maintained by massive cast-iron armour plates between the brickwork and steel buckstaves. The gas tuyères, air ports, and inspection plugs are attached to these armour plates by set screws, and

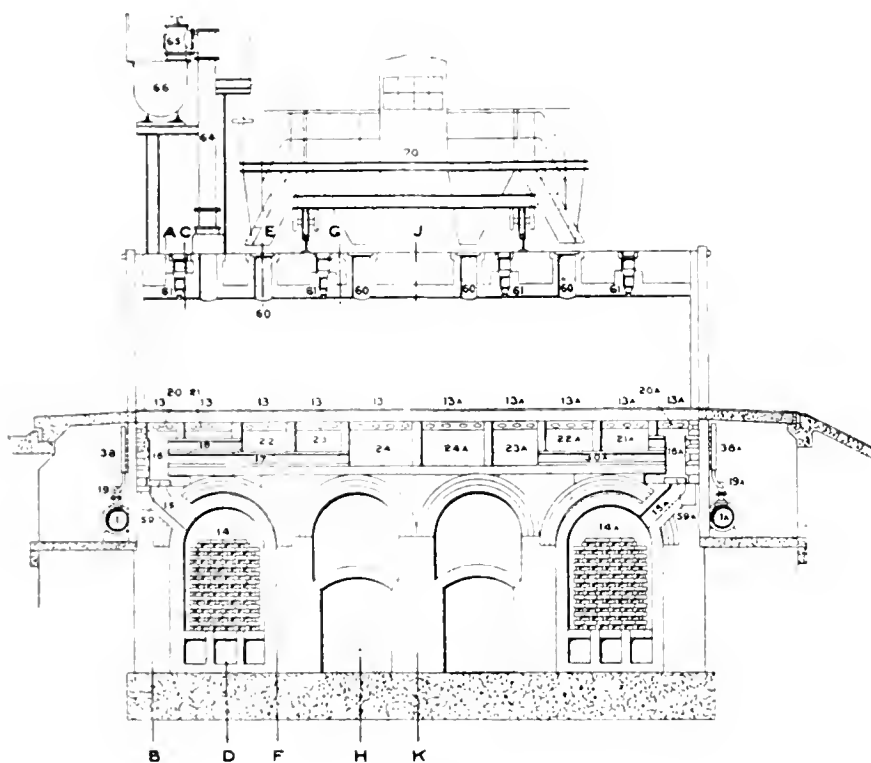

Fig. 4.

or waste heat oven is of similar design to the above—indeed it is covered by the same patents. In place of the regenerators there are two waste gas flues of smaller area. The arrangements for distribution of gas and air, regulation, and inspection are identical. The wall is divided into two halves, each served by one of the waste gas flues, and a number of the vertical flues at the centre of the wall (usually two) conduct the hot gases down to the sole flue and thence to the waste gas flues. The sole flue is not split up into sections, and the distributing canals for air and gas are side by side under the oven wall, but separated by an independent wall to render short-circuiting impossible.

are thus kept in place and proper alinement. By this arrangement the battery is less susceptible to the adverse influence of high winds in exposed situations, and retains its form at the doors with great advantage in the matter of luting and exclusion of air from the charge.

The gas and air for combustion are mixed in special tuyères referred to above, which are of Bunsen burner type and provided with regulators for both gas and air, before actually entering the oven flues. The intimate mixture so necessary is thus attained with certainty, and any extra oxygen which may be required in the lower flues due to partial saturation of the gases with CO , can be admitted. On the other hand, excess air can be

admitted to the top flue to avoid overheating of the oven crowns. By this means the heating effect of the gas can be increased considerably at the lower portion of the oven where the greatest amount is needed, without danger, as the lower air inlets give facilities for instant admission of excess air.

In practice it is scarcely possible to regulate and control combustion with such nicety as to obtain an absolutely even temperature throughout the length of the horizontal flues in this or any other oven, but the length of flame and facilities for regulation of air give a wide latitude and scope to the operator.

some form is common to nearly all designs of vertical flue ovens.

A second feature is the dividing off of each separate vertical flue from its neighbours at the bottom and provision of a separate gas nozzle in each which can be changed for regulation or renewal by means of a steel rod with key end through the top of the oven if necessary. A large sight-hole is provided outside the oven for inspection during operation.

The air entering the regenerators is evenly distributed over the bottom by means of ducts arranged and proportioned for this purpose, and rises evenly through the chequer-work to the dis-

Fig. 5.

The type is still popular, the opinion being held that it is not so delicate as the vertical flue oven either constructionally or in heat regulation. The large mass of brickwork surrounding the oven chambers holds a tremendous reserve of heat and contributes in no small degree to this, enabling rapid recovery after recharging etc.

The Koppers regenerative oven is of the vertical flue type with separate regenerators, and displays originality and the fearless spirit of the pioneer at many points. First among these, in my opinion, is the provision made for regulating the draught in each separate vertical flue by means of an adjustable damper on the top of it. The patentee realised the difficulty presented by parallel flows, and overcame it by controlling the draught in each flue just beyond the point where even distribution was of importance, or, as he put it in his patent claim, "the point of attack" of the chimney or draught producer on the flue or group of flues. At the present day this device in

tributing chamber under the sole of the oven. From here it passes through inclined openings into the bottom of each vertical flue, which it enters above the gas. By this arrangement good admixture is effected, and deposits of carbon in the gas jets avoided. Any deposits at the air ports can of course be easily burned away, but these are unlikely. I believe in some batteries the central flue was used for carrying a portion of the waste gases off for steam-raising purposes.

In the later ovens the air for combustion is admitted to the regenerators through separate cast-iron change valve boxes instead of through the flues with a change valve at the end of the battery. These separate change valve boxes are operated by wire rope from an automatically operated throw-over gear in exactly the same way as the gas-reversing valves. They admit air in one position with the gas outlet closed, and when reversed allow the waste gas to get out into the flue whilst the air inlet is closed.

The burning gases ascend in one-half of the wall and descend the flues in the other half. The Koppers regenerative gas oven and compound oven are similar in general design and arrangement to the above. In these, however, each regenerator

in sets of two of the air and gas regenerators makes for simplicity in the change valve boxes, which are alternate for air and lean gas, and avoids cramping of the gear.

The Koppers vertical flue waste heat oven is similar in design to the regenerative oven with regard to the vertical flues and arrangements for distribution and regulation of gas, air, and draught, except that the air is only preheated to a moderate degree by its passage through the conduit under the coke ram side of the battery and the flues under the oven sole. Gas is brought along the coke ram side of the battery only in a main and fed to the gas canals under each wall by large tuyères, which can be arranged to admit a small amount of primary air and thoroughly mix it with the gas. The secondary or main air supply is distributed to each vertical flue by cross passages, entering just above the gas jet. The gas burns upwards in all except two of the vertical flues and, descending the two at the coke bench side, is led through an inclined duct to the main waste heat flue and so on through boilers to the stack.

The oven may be arranged with waste gas flue under the ram track and air admitted from an observation gallery under the coke bench. In this case only one of the vertical flues is used for descending waste gases. It is an arrangement suitable for compressed charges in which the density is greater against the door at the charging side of the oven.

The latest development in the Koppers coke oven, and one which can be applied to either type, concerns improvements in oven wall construction and aims at rapid and uniform coking by the more efficient application of heat without sacrifice of strength and stability. The vertical flues in the oven walls are triangular in plan and staggered, as shown in fig. 7. Two independent parallel gas canals supply the burners along each wall, and the openings above are arranged so that the whole of each face of the flues along the oven wall can be inspected. The number of gas jets is increased, as also is the heating surface. A new method of bonding which is an absolute lock, and said to tie each side of the wall together in each layer of blocks independently of the blocks in the layers above and below, is also a part of the design. With these improvements the designers claim to have solved a problem which has been exercising the minds of coke-oven engineers for years. I am not in possession of full details, but it would appear from the above that a definite step forward has been made.

The Semet-Solvay waste heat oven is of horizontal flue type, and is illustrated by fig. 8. It is of exceedingly strong design and construction,

Fig. 6.

is divided by a vertical partition wall under the oven chamber, as shown by the sections on fig. 6. The regenerators under one oven serve for the lean gas, and those under the next oven for air. This destroys to a certain extent the independence of each oven, but this is of little importance in practice, as it is usually unnecessary to repair the regenerators or sole flues, and it is always necessary to lay three ovens off to repair the walls of one oven of this kind owing to the heat. In any case, the advantages of a clear separation of gas and air regenerators by the thick wall supporting the oven pillar, thus obviating all danger of leakage and short-circuiting, far outweigh considera-

Fig. 7.

tions of this kind. It is an arrangement common to most ovens of this type.

The cross-sections on fig. 6 show the differences in the three ovens, and also indicate the position of the rich gas canal and burners in the compound oven. It will be realised also that the alternating

Semet-Solvay oven. Waste heat type.
Fig. 8.

having firebrick walls of considerable thickness between the ovens and independent of the oven linings. These thick walls carry the weight of the oven tops, mountings, and charging cars, etc. Thus the linings are not subjected to excessive weight, and as each oven has its own set of heating flues each side, absolutely separate from those of adjacent ovens, repairs can be carried out without in any way interfering with them. Further, owing to the thickness of the division walls it is only necessary to lay one oven off at a time. In this oven also the mass of brickwork carries a huge reserve of heat, which means quick recovery after recharging.

There are five horizontal heating flues on each side of every oven, to four of which gas is supplied by tuyères connected to mains running along each side of the battery. Each of these gas inlets is made so that air can be admitted if necessary, but the oven is designed and intended to work on the principle of supplying a large amount of the total air required in the top flue. The object is to keep the top portion of the oven as cool as may be consistent with maximum yield of by-products. The top flue is also kept well below the oven crown for the same reason. Sight-holes are provided at each end of every horizontal flue so that the heating may be accurately regulated and the condition of the oven walls kept under constant observation.

The oven is partially recuperative as the air for combustion passes under the centre of the battery in the flue, C, and branches out under each sole flue in canals, D, to vertical ducts in the dividing walls supplying air ports close to each gas jet. These ports are so proportioned and regulated that the amount of air supplied to the top flue is greatly in excess of its requirements. By the time this excess air reaches the second and subsequent flues it has attained a high temperature and increased considerably in volume, the result being excellent distribution of heat, thorough mixing with the gas, and economic combustion with attainment of the highest temperature where it is required, at the lower portions of the oven walls. The waste gases combine in the sole flue, F, and then pass out to the waste gas flue under the ram track. Dampers are provided for regulation of draught.

The horizontal-flue oven of all designs has an advantage over vertical-flue ovens in the very important matter of thorough mixing, because of the length of travel of the combustible mixture and the change of direction at the end of each flue. At the same time, the area of the flues for a given heating surface is larger than in vertical flue ovens, which discounts to some extent this advantage. There is obviously a limit to which the principle of admitting a large excess of air at the top flue can be carried consistent with a reasonable percentage in the final waste gases and avoidance of undue losses, owing to partial saturation of the mixture with inert gases in the later stages. This compels the admission of primary air at the gas jets and a small amount of secondary air from the vertical ducts, or either of these. Nevertheless, I think that with the facilities for mixing the arrangement is an excellent one and capable of giving good results.

The Semet-Solvay regenerative oven is designed on similar lines with regard to the structure and arrangement of the flues and gas supply. The air is all preheated in the regenerators as usual, and during one period the gases travel downwards through the wall flues in the same way as in the waste heat oven. After reversal they travel upwards to the top flue, and thence by vertical down-take to the opposite regenerator. The regenerators are arranged athwart the battery in two sections for each oven, with two longitudinal flues

between them, which are used for air and waste gases alternately. In this oven the gas supply does not need reversal.

The C.G.O. (Coke and Gas Ovens, Ltd.) regenerative oven is of the vertical flue type. The general design commends itself as an admirable combination of the best established practice and sound theory in the aim to produce an oven which will meet all the demands of the present day. The essential principles of solidity and uniformity of stress under working conditions, already referred to, have evidently been kept in mind by the designers, while the important questions of heating surface, rapid coking, accessibility, and uniformity of heat distribution have received due attention.

The oven structure is supported on five massive pier walls and four arches forming tunnels, all of which are utilised as regenerator space. Thus maximum economic heating surface is attained without undue depth of foundations or any sacrifice of strength and stability. Uniform expansion of the whole structure is made possible, so that distortion and cracking are a minimum. Notwithstanding this, the regenerators are divided by cross walls into separate chambers, so that the advantages of independent regenerators are obtained. These separate chambers are two oven pitches in length, and those in the outer and inner tunnels serve alternate ovens. The hot air from the regenerators enters the sole flue at the centre of its length, so that distribution to the inclined ports leading to the base of each vertical flue is even.

The burning gases ascend the flues in one half of the oven wall and descend those in the other half. They collect in the sole flue under this half of the oven, and are led into the regenerator and waste gas flue under the regulating gallery and on to the stack. The outer regenerator chamber at one side connects with the inner chamber at the other side of the battery. Regulation can be made by the dampers between regenerators and waste gas flues, and also by the small damper blocks at the top of the vertical flues.

The C.G.O. compound oven follows the same principles of design and arrangement. The regenerators are subdivided so as to provide for both air and lean gas, as in the case of ovens previously described. An important difference, however, is that the gas and air are kept in separate tunnels, with the main walls of the structure between, so that leakage is impossible. This arrangement also makes it perfectly safe to keep the regenerators for both gas and air under the oven which they serve, whilst the sole flues are arranged in pairs, and the gas and air never approach each other until they issue from the ports for combustion in the oven flues. Separate cast-iron valve boxes are provided for both gas and air at each oven, and reversal is effected by wire ropes in the usual way. Independent regulation of air and waste gas is done by butterfly dampers, the setting of which is not affected by reversing. There are also sliding fireclay dampers, and dampers at the top of each vertical flue for distribution. The oven can be worked as an ordinary regenerative coke-oven, in which case all the regenerators turn on to air, and rich gas is supplied through the usual tuyères and canals which are always there in readiness. A small amount of rich gas can also be used in conjunction with lean gas if required.

The outstanding feature of the Otto waste heat oven is the method of distributing the gas with absolute certainty to the base of each vertical flue without any reliance whatever on chimney draught, and this principle is also applied in the regenerative oven. The whole of the oven structure is supported on continuous brick arches forming a platform like a wide viaduct, so that although the piers run at right-angles to the longitudinal centre line

of the battery there is little danger of damage through expansion. The spacing of these arches with relation to the oven pitch is such as to cause a very evenly distributed load on the arch rings. Openings in the pier walls and the access gallery under the coke bench make the whole basement into one huge cellar. The gas for heating the ovens is brought into this cellar by a main in the access gallery, and branch pipes from it feed the vertical gas tuyères under each pair of vertical flues. Each tuyère is provided with a regulating valve for the gas and a rotating shutter for primary air supply on the Bunsen burner principle.

The secondary air is admitted through a star-shaped brick in a fireday channel, which also serves to centralise the tuyère pipe. By this means intimate admixture of gas and air is effected, and perfect combustion under absolute control is the result. All the secondary air is drawn in round the gas nozzle by the influence of the chimney, and the only regulation is of gas and primary air and main draught on each oven. The hot gases ascend the vertical flues, traverse the top horizontal flue, and descend the two vertical flues at the coke ram side to the waste gas flue under the track. The sole flue is not used except when the oven is starting up or working as a non-by-product oven.

The Otto regenerative oven is built on arches forming a cellar in a similar manner to the former. The arrangements for distribution of the gas to the vertical flues are the same, except that there is of course no primary air admission. The regenerators are built outside the battery under the coke bench and ram track, and are of narrow and deep design divided into two parts by a vertical partition. Each half serves half the combustion flues in the oven walls with the object of securing a more even distribution of air. The waste gas flues run along one side of each regenerator, with which they communicate at intervals through special ducts provided with dampers.

Air is admitted to the regenerators from the cellar through separate openings, also provided with regulating dampers in addition to the reversing flaps. The waste gas is reversed by dampers at the end of the battery, and the same which reverses the air flaps and the three-way gas cocks between the main and the distributing pipes. There is no separate regulation of air distribution on this oven, but the arrangement of the inlet and canals is conducive to a very even draught, and the absolute control of the gas in the vertical flues obviously makes it possible to increase or decrease the temperature at any point within very wide limits owing to the amount of excess air necessarily admitted in all regenerative ovens operating on rich gas.

There is a constriction at the top of each vertical flue in the style which has now almost become standard, but no dampers or openings in the oven tops. These were found by actual trial to be unnecessary in this oven because of the perfect control of the gas distribution.

The gas burns upwards in one half of the wall, and descending the flues of the other half is collected in the double sole flue and led into the corresponding halves of the regenerator, dampers for general regulation of the oven being provided in the inclined ducts leading thereto. There is ample space in the cellar under the battery for regulation, inspection, etc. The gas tuyères can be instantaneously removed for cleaning without undoing any bolts or set screws.

The Otto combination oven for use either as a coke oven fired by part of its own gas or a gas oven fired by lean gas is of the vertical flue type with independent regenerators athwart the battery. I am not able to give details, but I believe a battery is under construction at the present time.

The concrete foundations for a battery of ovens should be reinforced with steel bars, old rails, or the like, even if the nature and strength of the ground does not demand it, on account of expansion. Even with the best provision for expansion of the battery there is the possibility of cracking the concrete, so that it becomes a series of disconnected blocks which may sink unevenly either on account of differences in the nature of the ground or the distribution of the load on same. Such reinforcement is frequently placed diagonally in two layers and considerably higher in the concrete than design for purely construction considerations would dictate. It is desirable to avoid wet ground, and any material of a combustible nature must be removed, whatever the cost or efforts in the direction of heat insulation.

General principles of design.

The first is that there should really be no such thing as a standard oven. The nature and properties of the coal must be taken into consideration first of all and the oven chamber and heating flues proportioned accordingly. For instance, the width of the oven is a most important matter, and may vary from 16 in. to 24 in. according to the class of coal.

If an oven is made too wide in an attempt to obtain "long" coke it may be found, as in certain Staffordshire seams for instance, that there is a most marked difference in the density at the outside and centre which will result in fracture with the least handling.

A very high oven is unsuitable for coals of indifferent coking properties, which have to be compressed, on account of the difficulty of making and handling the cokes. A long oven without taper is obviously unsuitable for coals which yield coke tending to be soft or friable, or which expand on coking.

The heating surface, as well as the number and arrangement of gas burners in the oven walls, should be proportioned to the requirements of the coal and the quantity, composition, and calorific value of the gas evolved. The area of the flues and ducts for gas, air, and waste gas should also be decided by these considerations. The position and capacity of the gas ascension pipe should also be settled from considerations of quantity to be dealt with and the maintenance of regular and correct relative pressure in the ovens.

There are many other considerations of this kind, but these will be sufficient to illustrate the point.

The coke oven is what engineers call a block-work structure. True, it is of a special type and subject to all kinds of stresses, both internal and external, which have to be provided for without recourse to internal reinforcement and are dependent on interlocking, tying, and bonding of the blocks for stability, when the stresses cannot be balanced against each other or neutralised by armature. This being so, it is a vital necessity to minimise the forces and arrange for their even distribution as far as possible and to relieve those parts of the structure subject to the greatest heat, and, therefore, in danger of softening and losing their strength, of as much external load as possible.

These parts are also where the maximum movement will take place due to expansion and distortion, and damage will be in proportion to the importance allotted to them as members of the structure. The best possible material is the cheapest, and adequate strength must not be sacrificed to space or rapid transmission of heat.

The structure should be looked upon as a series of retaining walls and arches, and the load, from whatever cause arising, should be transmitted to them in the proper manner for such. The design of any parts of the structure as beams should be discountenanced, and the use of large bridge

blocks avoided. It is urged that a minimising of the number of joints by such construction is a great advantage as tending to reduce the risk of leakage. When the difficulty of making, drying, and burning the blocks and keeping them true to size and shape, to say nothing of the contraction question, is taken into consideration, however, and also the result of the cracks which are almost certain to occur, it is seen that there is little, if anything, in the contention. Another and important point in this connexion is that all blocks do not turn out the same, and the results following the failure of a large block are much worse than in the case of a small one.

I do not advocate the use of exceedingly small blocks by any means. The blocks should be of reasonable and something approaching uniform size, which will tend to cheapen and speed up manufacture as well as be of great advantage in the finished structure.

In considering the general question of the design of a battery of ovens by far the most important and at the same time most difficult problem is that presented by expansion. This is not only on account of the ovens proper, but the surrounding structures and plant. The battery must stand alone, and although it may be used to support other work outside itself, allowance must be made for movement in three directions and it can therefore only support such things as can lift with it between times of adjustment without damage.

Attempts have been, and still are, made to gain support for the battery from the coke ram terrace or the coke bench. They will always fail, because the expansion is irresistible. Even if the above structures could be made of adequate strength the result would only be to damage the oven itself. Many ingenious devices and arrangements are resorted to with the object of providing for expansion within the oven structure without any alteration to its outside dimensions and shape. Their scope is limited, however, on account of the difficulty of accurately determining what that expansion will be. Therefore some external movement must be provided for if close brickwork and stability are to be attained. The longitudinal expansion of the battery is the most difficult to deal with on account of its direction with relation to the walls of the oven and the flues and canals below the sole. It also gains in importance with the number of ovens. The oven tops and the mass of brickwork at the oven sole have to carry the pillars or oven walls with them as they expand, and must do this without rupturing them if possible.

A good deal depends on the care with which the battery is heated up, and extra time and fuel given to this will be well repaid. It is not sufficient however, and special constructional devices have to be provided at intervals to "take up" the movement. All builders have their own well-tried arrangements, and it would be of little general interest to attempt to catalogue them. They usually take the form of a checked or halved joint between adjacent blocks at some well supported point. In building this is filled with material which will either partly burn away such as mixtures with pitch as a binder, or with material such as asbestos, silicate cotton, or dry sand, which will compress under high pressure whilst of sufficient strength normally to support the stresses put upon it during building operations. Careful calculation based on actual trial of the refractory material to be used determines the position, number, and "setting" of these expansion spaces, and they are carefully watched during building and heating up.

All parts of the oven structure are not subject to the same temperature, and changes of state of the refractory components are different, so that the amount of movement differs.

Thus from a variety of causes there is relative

movement between the bricks and blocks at different zones, and layers have to be designed to permit this to occur without damage or leakage ensuing. The arrangement of small air and gas canals so that they are not affected by such movement calls for careful study and experience, as even a small miscalculation might upset the eventual distribution and render it impossible to get good results in the heating and output of the oven. Worse, it may cause short-circuiting and fusion of the bricks.

Perfectly dry joints are not usually permissible unless the bricks are rubbed to a perfect fit as in gas retort and glass furnace practice. Usually a distinct cleavage can be obtained at a joint without this. One method is the insertion of paper, another powdered carbon. In the lower portions of the oven, on foundations, and at the end buttresses dry sand is used. It is necessary on occasion to provide for eventual expansion in the initial setting out of the ovens.

The bonding of the blocks in the oven walls equals in importance almost any other problem in coke oven construction. The object of all designs is to get the maximum "cover" by the use of a minimum number of different shapes, and to tie the actual linings together through the wall, and so make it as nearly equal to a solid wall in strength as possible. This has to be done without increasing the thickness between the flues and the oven face, which would tend to prolong the coking time.

It used to be considered essential to arrange the bond so that repairs or relining could be effected with a minimum amount of general disturbance of the wall as a whole. Experience has taught, however, that such considerations are insignificant compared to the advantages of strong construction and tightness. Therefore the use of ridges and recesses in both horizontal and vertical joints has become almost universal. Several different arrangements are shown in fig. 9.

The amount of clay used should be the absolute minimum practically possible. In the first place the clay, however treated, is different in actual composition to the bricks because of the chemical changes during manufacture of the latter. Changes in the fireclay in the joints are also bound to occur when the oven is heated up, and as the most important do not occur below about 800° C. a preliminary heating up followed by re-pointing with fire cement is commercially impracticable.

Secondly, as the clay has to be used in a plastic state, there will be water in proportion to its quantity to be driven off and shrinkage accordingly. This is partly distinct from, and in addition to, chemical change.

Thirdly, there is aeration of the clay, the bad effect of which is also in proportion to the amount.

Unless the bricklayers are carefully trained and constantly watched they will leave air bubbles or voids in the joints instead of making them solid, thus defeating the object of the use of all mortars, which is exclusion of air in order to attain more or less perfect contact and increase friction and stability. Furthermore, this air must expand on heating, and will find its way out where resistance is least, viz., at the joints. Subsequent leakage of gases will, of course, occur through the channels or pores so formed.

Armature.

The buckstaves and tierods for binding the brickwork have an importance greatly increased by the trend of modern design to deep structures due to size of ovens and independent regenerators. In the past they were nearly always too weak and of little use in maintaining the structure. In many instances the most glaringly unsuitable steel sections were used or old railway metals of inadequate strength. Buckstaves should, if possible, be connected at each extremity by tiebolts, so that the

binding of the oven brickwork is independent of anything outside the structure. This is seldom feasible, however, so the bottoms are fixed into the lower portion of the structure where movement due to expansion is a minimum. It is desirable, especially with the newer designs of ovens, to carry them right down to the concrete foundation; the tops being connected by tierods across the battery over the oven walls.

Fig. 9.

Their function is not the prevention of movement due to expansion—this is impossible—but the maintenance of the form of the battery, prevention of bulging, strengthening of the brickwork at wall ends by holding the blocks in firm contact with those further along the wall, closing of cracks due to periodic contraction, and compelling the taking up of expansion in the places designed for it, which the weight and friction of the outer ends of the wall might not be sufficient to do.

They are designed as beams, and much discussion has attended the question of determining the actual load which is likely to act on them. One method suggested was to assume a crack through the whole height of the structure at the angle of repose of loose broken firebrick on itself, starting from the buckstave toe; and calculate the conjugate thrust. Another, to find what diameter of tierrod would break and take the ultimate strength of it as half the distributed load; a third method probably more nearly accurate was to calculate the force necessary just to move a mass of bricks one quarter of the oven in length and of height above various horizontal planes, all assumed to be loose joints, and use these as loads on the beam. A German method was to work from the load which an equal depth of water would give and assume the centre of pressure reversed. None of these methods are accurate of course, but they are genuine attempts and as good as we have.

With silica oven construction the problem gains in importance on account of the amount of expansion. Adjustment of the tierods during heating up must be made, and it is best done by hardwood temporary washers. They should never be slackened right out. I know of two fairly recent cases of furnace collapse through a mistake of this kind. With silica construction we shall probably find it

necessary to provide for adjustment at the bottom as in glass tank practice owing to permanent expansion.

Exceedingly high refractory qualities are not the first essential for coke oven blocks as they are in the steel and glass industries. Contraction, whether due to imperfect manufacture or the nature of the fireclay, *i.e.*, high in alumina, is the bugbear of coke oven construction because the opening of joints cannot be satisfactorily dealt with. The leakages from this cause mean tremendous losses of rich gas when an oven is freshly charged and pressure cannot be avoided, and, later, destruction of coke and by-products, excess nitrogen and carbon dioxide in the gas, as well as great irregularity of heating and danger of fusion at all times.

In the old days managers became expert in blocking leakages with deposits of carbon by manipulation of draught and air supply, but frequently deposits occurred where they were not required, and this irritating juggling had to be constantly practised, as further openings were always developing. Complete repointing with carborundum, sodium silicate, and fireclay, or patent cement of a similar kind, was found to be of little avail. Some natural fireclays were found to be suitable and hold a high place still. Others were made suitable by admixture of silica and grog.

Many attempts were and are still being made to evolve mixtures which when suitably manufactured into blocks and burned will be without serious permanent expansion or contraction, and yet fulfil the other conditions required as to temperature, strength, and resistance to corrosion. Some of these have been very successful.

The silica oven was tried out in America and has come to stay. It is capable of being worked at high temperatures continuously, and, owing to its relatively high conductivity, rapid coking and uniform oven temperatures are easy of attainment. There is a very great expansion, but unlike contraction this can be dealt with. The expansion is of two kinds, *viz.*, that due to change of temperature only, which is temporary, and that due to change of state of the silica and its compounds at high temperatures, which is permanent.

There appears to be no doubt that the size of particles is of great importance, as fairly large pieces, or "peas," of free silica do not combine to the same extent with calcium in lime-bond silica bricks or the impurities in clay-bond bricks. The manufacturer must therefore discover the best grading from the standpoints of strength, homogeneity, and freedom from voids on the one hand and excessive fineness with danger of chemical change on the other. The question of porosity is also of importance because it is found that porous blocks do not spall so readily as the faced, and stand rapid changes of temperature better. It is also probable that a rough surface radiates heat better than a smooth one.

In spite of the difficulty with high-alumina blocks, a large battery was built with them and successfully operated in America, with, it is stated, excellent results. Such blocks would have great advantages in certain cases and may some day be adopted here. They are used of necessity in the glass industry, and special construction providing for the contraction difficulty is not beyond the bounds of possibility in coke-oven practice.

Working of the ovens.

For the efficient mixing of gas and air nothing in the direction of impinging or whirling jets arranged in the flues can equal outside admixture of gas and primary air, and the surrounding of the gas current with secondary air, particularly when using rich gas. If this is not done independent currents are certain, with the result that complete

combustion only occurs at changes of direction, which is often where great heat is not desired, such as the tops of the ovens and the sole flues. Sight plugs in accessible positions must be provided so that combustion can be watched while regulation is made, and the greatest possible amount of the flues must be open to inspection of the state of the brickwork without difficulty or inconvenience.

The three great anxieties of a coking plant manager are repairs, shortage of steam, and coal supply. The first two have already received treatment, and possibly the last forms a more fitting subject for a separate paper. Large storage bunkers, the contents of which are all accessible, are a vital necessity, however. They should at least be capable of holding three days' supply to tide over the week-ends easily without traffic troubles through blocked sidings.

The question of deterioration of the coal has, of course, to be considered, but in the majority of cases this is of rather less importance than continuous working. Whether by absorption of oxygen from the air or simple loss of methane, finely divided coal certainly does lose its coking properties as well as some of its calorific value. This is more marked in some coals than others and always worse the finer the coal. It may be minimised in several ways, such as mixing a proportion of larger coal with the slack, crushing immediately before use or at least at the top of the storage bunker, storage in comparatively air-tight ferro-concrete or steel bunkers after draining by mechanical means, such as the Baum conveyor, instead of in drainage bunkers or wagons, and the use of hoppers bunkers which are self-emptying.

The position of the storage bunkers depends largely on the system of charging the ovens and whether conveyors are to be used on account of mining etc.

It is necessary to compress some coals of different coking properties in order to make good dense coke. Even coals which yield a good coke without compressing are often improved by it, and, compared with hand charging from corves or dandies, the compressed cake is an excellent labour and time saving device, especially for large ovens. The upkeep of the machines, power consumption, and time required to make cakes, however, put it out of the running with the modern electrically driven top charging machines. These are capable, in conjunction with an efficient coke ram and leveller of dealing with six ovens of large size per hour, whereas only 3 or 4 at most can be managed when cakes have to be made.

The coal when charged into the oven should not contain more than about 10% of moisture. Some trials made by the author eleven years ago, on North Staffordshire coal, showed a difference of over 1% in the amount of breeze produced, due to difference of moisture content.

The position, size, and length of the gas ascension pipe needs attention; it is a mistake to put it at one end of the oven, especially when the latter is filled as high as possible. Convenience in the arrangement of the method of charging should not be allowed to dictate this. Far better have two separate cars, or, better still, two ascension pipes and collecting mains, one each side of the battery. There would be no difficulty in this on the score of cost when two qualities of gas were required, and it would be worth the expense in other cases owing to increased yield of by-products and output of coke through regularity of working. The quantity of gas given off in the first few hours is much greater than towards the end of the coking period, and, in addition, there is a very large volume of steam. Thus high pressures are the rule immediately after charging, which give a great deal of trouble in luting doors and charging holes and even so result in losses by leakage into the atmosphere and the

combustion flues. Similarly, in the later stages air leakages occur through excessive suction and the unavoidable neglect of the luting.

I do not think the fact is generally realised that the early part of the coking period is the most efficient looked at from the standpoint of the application of heat, because of the greater temperature difference. Everything possible should therefore be done to make the most of this. Even a small difference of pressure makes quite an appreciable difference in the distillation of substances like coal. This leads to the question of oven isolating valves which can be regulated, in conjunction with larger ascension pipes. These have been adopted by at least one of our leading firms.

The mushroom type of valve is scarcely suitable owing to the large increase in area for a small movement and consequent danger of blockage. The butterfly type is better in spite of some disadvantages. The flat bench on to which the whole mass of coke was pushed, pulled over, and quenched by hand, is now obsolete.

As the size of coke-ovens, number per battery, and speed of coking all increase mechanical means of quenching and loading coke become more necessary. The manual labour problem also compels their use. I shall therefore briefly describe one or two:—

1. The inclined bench covered with smooth cast-iron plates and set at an angle down which the coke will slide on to a tray conveyor at the bottom, is a good arrangement provided the conveyor is of sturdy construction and has working parts capable of resisting the rough wear of fine coke dust and water. In case of breakdown there is room to store the coke whilst repairs are carried out. The conveyor is usually inclined at one end in order to gain the elevation necessary to deliver over bar screens for separating breeze, into ordinary trucks or blast-furnace skips. The bottom portion of the bench is arranged as a tilting flap, which retains the coke on the bench in one position and acts as a shoot on to the conveyor in the other. These flaps are in separate lengths and operated from the gangway outside the conveyor.

2. The Coppée coke screening and loading machine is arranged to travel by electric power the whole length of the inclined coke bench. There are gates at the bottom of the bench operated from a gangway, which deliver the coke and breeze into a continuous bucket elevator. This raises it to a sufficient height to deliver over a bar screen into trucks or blast-furnace skips on a track outside the machine. The breeze is collected in a box below the screen and discharged at intervals into separate wagons. The screens and shoots can be arranged to deliver both large coke and breeze into wagons on the same siding. Where space demands, or it is desired for any reason, a vertical self-tipping hoist replaces the bucket elevator. In hilly country the machine can be arranged without either, the whole movement of the coke being by gravity. The makers claim a great saving in cost of coke loading, the machine being operated by one man, facilities for selection of any batch of coke on the bench on account of quality or the position of wagons, rapidity of loading (the rate being 25 tons per hour), simplicity of construction and operation. The machine is also away from the steam from the quenching operation.

3. Another type of coke car consists of a shallow steel car with inclined bottom, and is in effect a short portable coke bench. There are gates at the bottom of the slope to retain the coke, which is thinly spread out over the bottom of the car by slow translation of it along the battery as the coke is discharged from the ovens through a Darby type quencher. The object of this is to allow for cooling and steaming off, and to this end the area of the car bottom is made as great as pos-

sible. There is usually an incline at the end of the track up which the car is hauled by wire rope to deliver over bar screens to coke wagons below.

4. The Goodall quenching and loading machine consists of a rotating table on to which the coke is pushed through a quencher of ordinary type. The movement of the table whilst the coke is passing on to it parts the pieces gently and spreads the coke out in a thin layer to steam off and cool. There is a steel cylindrical casing round the table about 6 ft. high, so that no direct air current can play on the coke at this stage. There is a wide shoot on the side of the machine remote from the ovens, with jiggling screen and breeze boxes below. The portion of cylindrical wall of the machine opposite this shoot is loose and pivoted at one side. When coke is to be loaded into wagons the table of the machine is rotated in the reverse direction, and the free end of this loose piece at the same time slowly travels towards the centre of the table, thus forming a plough and guiding the coke down the shoot. The whole machine travels by electric power on rails along the battery and can receive coke from any oven and deliver to any wagon, thus permitting selection of specially good quality and avoiding necessity for shunting of trucks. It effects great saving in the cost of coke handling.

5. The size of ovens and number per battery, also the rapidity of coking under American conditions, has compelled the adoption of high-speed coke handling, and it has been found that no system in which coke was allowed to remain in close proximity to the ovens was possible. With ovens coming off every few minutes, it will be realised that freedom from any incumbrance, such as coke cooling off and steaming, is vital. The best arrangement, and one which now finds most adherents, is central quenching; i.e., the coke is not quenched as it leaves the ovens, but taken to a central quenching station, at high speed, in a special coke car, to be quenched and afterwards either spread on a coke bench apart from the battery or delivered direct to screening and loading plant.

In a typical arrangement of this kind, constructed by Messrs. Simon-Carves, Ltd., the coke is discharged from the ovens by a very powerful high-speed ram in about half a minute, through a coke guide, which is like the ordinary quencher without water, into a short and deep coke car. This car is rushed at high speed along a horizontal track by electric locomotive to the quenching tower. This is a high, chimney-like structure, usually of ferro-concrete and provided with large water tanks round the central chimney, at the top. A measured quantity of water is instantaneously doused on to the coke in the car, which is then conveyed to the wharf and on to the screening plant by tray conveyor. The gates at the front of the sloping bottom of the car are pneumatically operated by the driver of the locomotive, so that no time is lost, and the car returns to the ovens for the next batch. Such a car is capable of serving a battery of 150 ovens.

A novel form of screen, called the "grizzly," is being put forward in connexion with this plant, consisting of a series of shafts set slightly below each other and parallel to the track on which the coke car runs, or the feeding conveyor. On these shafts discs are threaded at intervals of an inch or so and meshing alternately, so that the appearance in plan is a huge grid. These shafts rotate at different speeds, that at the top being the slowest. The result is that the coke is drawn from one on to the other in the same manner as fabrics in many devices used in the textile industries. The breeze falls through into hoppers, and the large coke is gently lowered without risk of damage into wagons or furnace skips at the bottom end of the screen.

In conclusion, I wish to express my thanks to the various firms of coke-oven engineers for the loan of

slides and drawings and courtesy in giving me information asked for.

THE MORE ECONOMICAL UTILISATION OF COKE-OVEN AND BLAST FURNACE GASES FOR HEATING AND POWER.

BY G. W. HEWSON, A.I.MECH.E., AND S. H. FOWLES, A.M.I.MECH.E., A.M.I.E.E.

We shall endeavour to show in this paper that in the manufacture of metallurgical coke, and in the use of such coke after leaving the oven, large quantities of gas are produced which can be more efficiently utilised than is the practice at present.

Professor Bone states that in 1913 the output of pig-iron in the United Kingdom amounted to 10·48 million tons, from which 7·66 million tons of steel was made. The average coke consumption amounted to about 25 cwt. of coke per ton of pig-iron produced. The corresponding amount of coal would be about 37·5 cwt.; thus the total coal used in producing 10·48 million tons of pig-iron would amount to 19·65, or, say, approximately 20 million tons. In 1916 Professor H. E. Armstrong stated that "fully two thirds of this coke is now produced in recovery ovens of various types." This leaves one third still being produced in the wasteful beehive ovens—a figure confirmed by the Nitrogen Products Committee—and it is safe to assume that all the recovery ovens in use are not working upon the most economical lines.

Taking these figures as a basis, the potential possibilities, after supplying the needs of the coke-ovens and the blast-furnace, may be stated thus: *From the coke-ovens:* $20 \times 10^6 \times 5000 = 100,000$ million cb. ft. gas at, say, 500 B.Th.U. per cb. ft. *From the blast furnaces:* $10 \cdot 48 \times 10^6 \times 75,000 = 786,000$ million cb. ft. gas at, say, 100 B.Th.U. per cb. ft. These figures assume 5000 cb. ft. of surplus gas from the ovens per ton of coal carbonised, and 50% of 150,000 cb. ft. of surplus gas from the blast-furnace per ton of pig-iron produced.

How best to utilise the enormous potentialities of these gases requires careful consideration. Engineers in this country have had more extended experience in steam plants than in gas engine plants, whilst the reverse is the case on the Continent. There the large gas engine using coke-oven gas is more popular, and the special difficulties in dealing with a rich gas with a high hydrogen content have been overcome.

Use of coke-oven gas.

The following have been taken from Brame's "Fuel" as average figures obtained on several classes of work, and we consider they represent good average working:—*Steam:* Steam raised per lb. of coal carbonised, 1·25 lb. Steam required per h.p.: reciprocating engines 15 lb.; turbines 11 lb. H.P. per ton of coal = 187 and 255 respectively. *Coke-oven gas:* Surplus gas per ton of coal carbonised 5000 cb. ft. at 500 B.Th.U. Heat units required per h.p. 9500 (27% efficiency). H.p. per ton of coal = 266.

In tests made at Messrs. Cockerills, 1 kw. at the terminals consumed 35·3 cb. ft. of coke-oven gas at 450 B.Th.U., approximating 9000 B.Th.U. per h.p. on the gas engine with 95% efficiency of the generator.

Dr. H. G. Colman gives the consumption with 458 B.Th.U. gas on a Nürnberg engine of 1200 h.p. at 100 r.p.m. as 21·3 cb. ft. per h.p., equalling 9750 B.Th.U. per h.p.

These results were actually obtained on long runs quite apart from test figures, and give quite a good lead to the internal combustion motor over other prime movers.

Professor Bone in "Coal and its Scientific Uses" points out the possibility of saving 0.9 ton of coal per ton of iron produced by having the coke-ovens in close conjunction with the iron and steel works, instead of at the colliery, and by utilising the surplus gases from the ovens mixed with blast-furnace gas for heating the steel furnaces and soaking pits, and for generating power.

We agree that blast-furnace gas alone should be used for gas engines in the power house for reasons which we shall state later, and the surplus coke-oven gas will be better employed in heating steel furnaces and soaking pits, either alone or diluted with blast-furnace gas.

Open-hearth steel furnaces have been successfully operated with coke-oven gas, thus effecting a considerable saving against producer gas. Other advantages are that coke-oven gas is anhydrous and low in sulphur, and it is possible to provide a reducing atmosphere over the bath, which is a decided advantage in the production of high-grade steel, excessive oxidation and decarbonisation being prevented. Coke-oven gas does not require preheating; it suffers decomposition, and its calorific value is reduced by 25–33% if preheated in the gas chambers of an open-hearth furnace. The manganese consumption is lower throughout than when working with producer gas. In addition, a saving is effected in refractory bricks, in wages, and in steam.

On the basis of 8000 cb. ft. of coke-oven gas required for making 1 ton of steel and 4300 cb. ft. for reheating furnaces per ton of steel, the quantity of coke-oven gas potentially available is sufficient for about 8 million tons of steel per annum.

The purpose for which surplus coke-oven gas is actually used is largely dependent upon the location of the ovens. The demand for such gas may be sufficiently great in some instances to make the gas a more important product than the coke. In such cases the plant would actually be a by-product gas plant.

The production and utilisation of blast-furnace gas.

The relative proportion of blast-furnace gas made and utilised profitably in Germany and this country in 1911 was—

	Germany.		England.
	B.H.P.		B.H.P.
Produced ..	1,340,000	..	1,060,000
Utilised ..	448,000	..	23,000

In 1911 the total power production from blast-furnace gas in large gas engines was 1,033,509 b.h.p., of which Germany contributed 46.5%; America 32.5; France 5.4; Belgium 4.6; Austria Hungary 2.4; Great Britain 2.4; and other countries 6.2%.

The quantity of gas produced in a blast furnace using coke as fuel, is usually considered as approximately 150,000 cb. ft. per ton of iron produced; this may be materially increased if the blast furnace is considered as a gas producer, since the use of blast-furnace gas for the production of power, and its more economical use as fuel gas has materially altered the necessity for economy in the use of coke in order to keep down the cost of manufacture of pig iron. It has been demonstrated that by a more intensive working of blast furnaces, by increasing the coke in the charge, and, incidentally, the yield of pig iron, blast-furnace gas could be improved in calorific value. Trials have shown that by increasing the coke 18% an increased metal yield of 7% is obtained without affecting the quality of the iron, together with 15% larger volume of gas, with its calorific value raised 12%, the heating power of the total gas produced being increased 25%. Hitherto all the gas produced by a blast-furnace plant has been utilised on that plant alone, and in some cases has been augmented by the use of coal on boilers to raise steam for the blowing engines and auxiliary plant.

With modern and more efficient modes of utilisation at least 50% of the gas is released for purposes outside the blast-furnace requirements. This is equivalent to 25% of the heat value of the coke charged into the furnace. This economy results from the higher temperature attainable in the stoves by means of a smaller consumption of gas. Compared with stoves working on dirty gas, and requiring 50% of the gas produced by the furnace, modernised stoves working on clean gas have given higher temperatures to the blast over longer periods, with a consumption of 28–30% of the gas produced. In spite of the loss of the sensible heat of the gas, and allowing 12% for the blowing engines and 8% for leakage, losses, etc., there is available for power generation or other purposes 50% of the gas made. If, however, the blowing engines are not gas driven, then the quantity available will be reduced considerably, if not entirely wiped out.

Increase of our knowledge of blast-furnace gas should give an impetus to the construction of internal combustion engines and gas turbines. The most recent guarantee figures for large water-tube boilers give about 218 cb. ft. of blast-furnace gas at 100 B.Th.U. per cb. ft. as the lowest requirements per kilowatt generated with turbo-generators, which gives a thermal efficiency of 15.5% over boiler, turbine, and generator; while to-day, with gas engines at 10,000 B.Th.U. per b.h.p. hour it is possible to get an efficiency of 25.5%.

The number of engine-room attendants required is the same in each case, but more attendants and cleaners are wanted for boilers and turbines. The maintenance and repairs on gas engines are sometimes greatly in excess of that for turbines, but this does not apply to engines working on clean blast-furnace gas. Two engines have recently been examined after running without any trouble for 15,000 hours each, and they required no cleaning. Other engines have run on this clean gas for equally long periods without requiring the gas throttles cleaning.

Again, the greater efficiency of the gas engine more than compensates for the loss of sensible heat due to the necessity of cooling the gas for the engine, against retaining it for boiler use. It has been computed that on an average about 7% of the heating value of the gas is lost by cooling it. Taking 1 cb. ft. at 100 B.Th.U. cooled by engines, we get $(100 - 7) \times 25 / 100 = 23.25$ useful B.Th.U. in the engine; hot gas for boilers gives $100 \times 15 / 100 = 15$ useful B.Th.U. in the turbine. Comparing the thermal efficiency of gas engines with steam turbines, we see what a saving can be effected by the former, and this points to the importance of installing the most efficient machinery to utilise the gases evolved from the blast furnaces of the country.

Comparison of thermal efficiencies.

	Efficiency.		Ch. ft. blast-furnace gas reqd. to give 1 theor. h.p.
	%		
Large gas engines ..	25	..	114
Large turbines with boilers ..	15	..	190
Small " " " " ..	12.5	..	228

Taking two plants of similar capacity, producing and cleaning approximately the same amount of gas, the following comparisons have been compiled from actual experience of the use made of the gas:

	Use of gas.	Gas engine plant.	Boiler & turbine plant.
On stoves	45%	45%
On blowers	28%	55%
On electrical generators	27%	nil.

The main factors which render blast-furnace gas when properly cleaned such a good fuel for gas engines are:—(1) Freedom from tar and from dust. (2) Regularity in quality or calorific power. (3) Comparative constancy of volume. (4) Freedom from premature explosions, even under compression. (5) Lower temperature of the exhaust gases.

It has been demonstrated recently that if our existing plants were modernised, and brought up to a reasonable state of efficiency, the saving would approach the saving of power anticipated from the super-power station scheme.

We venture to suggest that, from a national standpoint, it would be better to harness all the potential power of the 300 blast furnaces at work in this country and, linking up with existing power companies, supply the country with a large proportion of its requirements at a more reasonable rate than is at present possible with stations using coal-fired boilers and turbines. It has been stated recently on high authority that if the steam turbine be increased from what is considered a reasonable size to-day, viz., 15,000 h.p., up to 60,000 or 70,000 h.p. the steam consumption can only be reduced $\frac{1}{3}$ lb. per kw. generated, which is a very small amount compared with the increased size of unit.

This large size of unit has another great disadvantage, that if with a station of two such units one set fails, serious inconvenience will be caused, even allowing for the possibility that such a plant may be linked with the greater scheme. Again, some of these larger stations may be built at a distance from the coalfield, and this will not mitigate our transport difficulties.

In order to compare the generation of electricity from blast-furnace gas with the capacity of existing or prospective power stations, the following table gives the units generated and consumed over a period of four weeks, using the surplus gas from three blast furnaces:—

Units generated	1,450,000
Consumed by steel works	540,000
.. .. shipyard	400,000
.. .. blast furnaces	230,000
.. .. gas cleaning plant	90,000
.. .. power station auxiliaries	30,000

Apart from cost of running, the reciprocating gas engine is more in favour as a blast engine than the turbo-blower from the blast furnace view-point.

The cleaning system.

Of equal importance with the type of engine to instal is the question of the most efficient type of cleaning plant. There are three principal systems, viz.:—The electrostatic, the wet washer, and the Halberg-Beth.

In the opinion of the authors the Halberg-Beth is pre-eminently the most efficient plant for cleaning blast-furnace gas. The plant they have been associated with has run successfully and smoothly for three years, and they are satisfied that with proper care and attention it will continue to do as well in the future.

The electrostatic system, while retaining the sensible heat, has not proved the possibility of cleaning sufficiently low for engine consumption. The best that can be hoped for is 0.3–0.6 gram of dust per cb. m. of gas. Taking into consideration the large quantities of gas dealt with over a period of months, even this comparatively small amount reaches a large quantity and will cause trouble in stoves or boilers, much more so in engines. The wet washers require a large amount of water to clean the gas for engines.

The Halberg-Beth plant gives gas cleaner than the surrounding atmosphere, often for long periods not exceeding 0.001 g. of dust per cb. m.

If all the power is cut off the cleaning system would pass dirty gas, the wet-washer would soon choke up, while the Halberg-Beth plant continues to supply the engines with clean gas. With the Halberg-Beth, 5% of any unit can be shut off for repairs, and the remainder continue working. This cannot be done by other systems.

In order to emphasise the superiority of gas engines over boilers and turbines, the following

table of comparative costs is given, starting with the same cost of preparation of the gas.

A. Cleaning 3 million cb. ft. of gas per hour by the Halberg-Beth plant.

First cost of plant, £62,000.	£
Interest on outlay at 7%	4340
Depreciation at 10%	6200
Power and light at 35 k.w. per mill. cb. ft. and 0.5d. per unit	1860
Plant labour costs	1064
Dust house costs	1560
Supervision	300
Repairs and stores at 6d. per mill. cb. ft.	638
Renewal of filter bags, one set per annum	900
Steam for reheating 0.2 lb. per 1000 cb. ft. at 2s. per 100 lb.	510
	£17,972
Less cost of boiler and flue cleaning	1594
Less cost of stove cleaning and lining	3360
Less revenue from sale of dust	4411
	9365
Net cost of gas cleaning per annum	8607
Cost per 1000 cb. ft., 0.081d.	

B. Cost of generating 1 B.Tr.U. of electricity from blast-furnace gas, using gas engines.

First cost of engines, £55,000.	£
Interest on outlay at 7%	3850
Depreciation at 10%	5500
	£9350
Load factor 40%	Pence.
Engine cost per unit	0.102
Value of gas used	0.075
Cleaning of gas	0.012
Labour	0.055
Maintenance	0.008
Oil and stores	0.054
	0.306

C. Cost of generating 1 B.Tr.U. from blast-furnace gas, using boilers and turbines.

First cost of boilers and turbines, say 75% cost of gas engines, £41,250.	£
Interest on outlay at 7%	2887
Depreciation at 10%	4125
	£7012
Engine cost per unit	Pence.
Value of gas used	0.078
Cleaning gas, 218 cb. ft. at 0.081d. per 1000	0.109
Labour	0.017
Maintenance	0.110
Oil and stores	0.016
	0.054
	0.384

Conclusions.

By building coke ovens near the blast furnaces and steel works upon the regenerative principle, about half the gas generated can be utilised for the latter. Further surplus gas might be released if the ovens were fired with gas produced from inferior fuel, unsuited for other purposes than conversion into producer gas.

With cleaned blast-furnace gas, better results are obtained on the furnaces themselves, as the result of higher and more regular heats being obtained upon the stoves. More regular blowing is possible with gas-driven engines than with the old steam engines.

By means of clean gas the requirements of the blast-furnace plant can be easily met, and surplus gas is available for other purposes, preferably for the generation of electricity by gas engines, and can thus supply all the power required by a modern iron and steel plant.

The production of electric steel, or the finishing of steel manufacture in an electric furnace, is gaining favour in America, and it appears to the authors that the policy they have advocated may lead to an impetus being given in this country to the finishing of steel manufacture in an electric furnace, which, as a piece of apparatus for refining steel, has no competitor.

Discussion.

Mr. J. E. WEYMAN said there was no doubt that the Halberg-Beth system of cleaning blast-furnace

gas had been successful, but a later American plant was said to be more effective, there being no cooling of the gases.

Mr. E. E. Wood asked the authors on what authority they stated that to make one ton of steel required only 8000 cb. ft. of coke-oven gas; his own figures were at least 20,000 or 30,000 cb. ft. The authors' figures showed a gas engine to be a more economical proposition than a steam turbine, but the figures which he had obtained showed just the contrary. The question of the relative efficiencies of the two was a very debatable one.

Dr. G. S. WEYMAN said that coal for coke ovens must be suited to the product, and the sulphur, ash, and phosphorus should be strictly limited. It was not necessary to be so strictly limited in coal gas manufacture in the ordinary way. The coal for gas works need not have any coking properties. If all the gas works were replaced by coke ovens a certain amount of coal would not be available for coke ovens and, he presumed, would become a drag on the market.

Mr. Hewson, replying to Mr. Wood, said that the figure of 8000 cb. ft. of coke-oven gas per ton of steel had been given in the *Journal of the Iron and Steel Institute* in 1914, and confirmed by Sir Robt. Hadfield.

Mr. FOWLES added that the American gas-cleaning plant referred to had not yet proved suitable in this country. By the adoption of the Halberg-Beth system they were saving about a penny per unit on the system; they had been buying at a 1½d., and were now producing at less than a farthing. Blast-furnace managers who had formerly preferred the steam turbine now preferred the gas engine, as it kept the burden of the furnace free. As regards gas engines versus steam turbines, he stated that the Newcastle Electric Supply Company, who for years had used the waste gas under boilers, now used gas engines with excellent results. The gas engine had suffered in the past because it was not properly handled and looked after, nor was the gas properly cleaned. In using blast-furnace gas they were free from tar troubles, the engines required little cleaning, and there was the additional advantage of the potash recovered.

COKE-OVEN GAS FOR TOWN SUPPLY.

BY HAROLD E. WRIGHT.

The object of this paper is to deal with the economic application of coke-oven gas to town supply.

If the true economy of our fuel resources is the main consideration, then the regenerative type metallurgical coke-oven stands first as a means for producing town gas with the least waste of the original fuel. In round numbers the relative efficiency of the various methods expressed in percentage heat units of original fuel remaining available in the final product is:—(1) Regenerative coke-oven 90%; (2) average gasworks plant 85%; (3) average gas plant afterwards converting all surplus coke to water-gas 55%; (4) water-gas plant 49%. The steaming of retorts and the making of water-gas are directly opposed to the conservation of fuel. This procedure is also only made financially practicable if town gas is sold at prices very much exceeding its true fuel value. The cost of distribution and general charges which can be reduced *pro rata* by increased sales are important items in a gasworks' cost account. The true reason that gas is not more largely used for heating and cooking by the public to replace coal and coke is because the latter means is less costly, and if the economic policy of gas manufacturers were directed to providing gas at a cost nearer its heating value, they would by thus encouraging consumption reduce one of their principal costs. This is a strong argument in favour of the use of the regenerative coke

oven for manufacturing gas for town supply, where it is possible to adopt it, because in a proper economic situation it can supply gas for town use at a price very little in excess of the cost of distribution and general charges. On the other hand, it is unfortunate that it may only be economically sound to adopt this method at a limited number of places for reasons stated later. In the regenerative coke-oven the surplus heat from the combustion of part of the gas to carbonise the coal is retained by reversible regenerators, and this being carried back to the oven walls by the air supplied for combustion releases all surplus heat as surplus gas. The actual gas realised varies with the quality of coal used. In the average case the surplus would be 55% or about 6000 cb. ft. per ton of coal. By proper construction of ovens and regenerators to enable producer gas to replace the gas used in heating the ovens, all the coke-oven gas could be obtained as surplus, but there is no saving of thermal units in this procedure—rather the reverse. Therefore, unless the gas so liberated can be sold at a higher price than the cost of the producer gas required to liberate it, this proposition is economically unsound, and from the point of fuel conservation it is totally unsound.

Where surplus coke-oven gas is available at adjacent coke-oven plants under separate control, the quality of which can be readily ascertained, its use for supplementing or replacing existing gas supply is a mere matter of ascertainment and bargaining. Public authorities so placed can most probably secure a supply of gas at a lower price than their existing plant can manufacture it. This, however, is only likely to be the case in isolated instances. The general case will require coke-oven plant to be installed and existing gas manufacturing plant replaced.

Of course this cannot be applied to every case, because many points need very careful consideration before the change is made. A few such points may be outlined. Successful coke-oven undertakings derive their revenue from the sale of metallurgical coke, and only in areas where such fuel can be sold readily can they succeed. There must be a ready demand, as continuous operation is necessary to the success of coke-ovens. In my opinion the coke-oven cannot be successfully operated to produce inferior coke.

The coal for coke-ovens must also be suited to the product required. The sale of metallurgical coke becomes much more difficult as the ash in it exceeds 10% and the sulphur 1%. On this account many good gas coals are not as suitable for coke-oven use. With this limitation on the coal supply the regenerative oven calls for twice the amount of coal to produce the same gas, and this in many cases will present great difficulty to-day.

Each separate case thus opens up difficult phases demanding the highest commercial and technical judgment to be applied to the study of the varying factors likely to operate for and against the proposal. The substitution is probably only worth considering where much extension or renewal of manufacturing plant is contemplated, and then only when the regular supply required is fairly large. Thus it is to be feared that all the chief influences will in general operate collectively against the introduction of the thermally more efficient coke-oven method of gas supply. There will be cases favourably placed, and the following matters should enter into their consideration.

The main economic difference between gas plant and coke-oven is that in the former handling of material and charging and drawing retorts etc. is done piecemeal and by a much more complicated method and at double the cost of the simple and large operations in coke-oven practice. The coke-oven derives its principal revenue from the sale of coke, while at a gasworks the sale of coke seems to be rather neglected, the principal revenue being made from the sale of gas.

Changes in costs and prices to-day are so kaleidoscopic that it appears preferable to illustrate this by figures drawn before the war than to attempt any present-day estimate. The following figures therefore represent the operation of a coke-oven and gas plant in the same area where cost of carriage on coal from the collieries is equal to both cases. In both cases the cost of the coal used is represented as 100, and the other figures are given comparatively, assuming 2 tons of coal in coke-ovens as required to yield the same gas as 1 ton in gas practice or, say, 12,000 cb. ft. per ton and per two tons, respectively:—

<i>Carbonising cost.</i>		
	Gas plant.	Coke-oven plant.
Cost of coal	100	200
Manufacturing cost	26	24
Interest, redemption, etc. ..	10	24
	136	248
Profit on sale of coke and breeze ..	45	200
Profit on sale of tar and ammonia ..	24	48
	69	218
Nett cost	67	Nil
<i>Purification, distribution, and general cost:—</i>		
Purification and general charges ..	65	
Interest, redemption, etc., on general plant ..	36	101
Plus loss on carbonisation as above ..	67	
	168	
Less:—		
Sale of gas	162	
Income from other sources ..	6	
	168	

It is obvious in this case that the coke-oven plant could pay all gasworks costs on distribution etc. plus the 10% for interest, redemption, etc. on gas plant laid out of use, and sell its gas at 101 instead of 162 without actual loss.

The chief point to note in these figures is the great difference in value received for coke which makes the above reduction in price of gas possible. The consumption and distribution cost on gas in the gasworks case appears to be handicapped in competition with their own coke, because roughly 8 B.Th.U. can be bought as coke at the same price as 1 B.Th.U. in the gas.

We have now to deal with the quality of coke-oven gas and the question whether it can be wholly used for town supply. Average coke-oven gas from which benzol and its homologues have not been removed only differs from coal-gas resulting from the destructive distillation of coal in a plain retort in that it generally contains about 5% by volume more nitrogen. If the benzol is extracted the illuminating value is low, but when this is not done average coke-oven gas can be taken as generally equal to the gas supplied in any town to-day, because the latter is a mixture of coal-gas with water-gas more or less carburetted. Further, it is possible to control and improve the quality of the portion of coke-oven gas taken for town supply if proper arrangements was made. Without going into close detail, in coking Durham coal it is found that illuminants rapidly diminish after the first half of the coking period. Methane diminishes, being replaced by hydrogen after two-thirds of the coking period. It is only in the final stages that nitrogen increases rapidly.

Probably the first offer to supply coke-oven gas on a large scale for town supply in England was made by Sir B. Samuelson and Co., Ltd., in 1903. They offered to supply gas to the Middlesbrough authorities to the extent of 800,000 cb. ft. per day at 7d. per thousand feet. The offer was not accepted, and as the official gas costs went on showing well over 8d. and up to over 9d. for some years the conclusion was that it may have been rejected on the score of quality. Therefore in 1912, when the company was considering the replacement of some old ovens, the question was reopened, and the suggestion made to overcome any objections on account of quality by setting apart the gas from

the early coking period for town use. To prove the effect of this on the quality of the gas the following experiments were carried out on an existing set of ovens. As it was decided to leave the benzol etc. in the gas supplied to the town, the extraction of benzol was discontinued by stopping the flow of oil on the benzol recovery scrubbers. The gases from ovens of lengthy coking period were shut off the main and blown away into the air during the time of the test:—

	Candle-power.	Gross, B.Th.U. per cb. ft.	nett.
Average gas before the test ..	8.8	541	498
Gas from ovens under 21 hrs. coking ..	10.9	579	535
" " " 18 " " ..	12.7	612	564
" " " 15 " " ..	14.1	647	598
" " " 15 " " ..	15.0	669	619
Average gas after the test ..	11.1	572	524

These experiments proved conclusively that by the provision of separate mains so as to isolate the gases from the early and later coking periods the quality of the gas supplied for town use could be controlled. The author would advise that this provision should be made if regularity of quality and especially illuminating value are in future to be considered of importance in town supply, because if the provision is not made there may be fairly large variations at times. Coke-ovens are exposed to atmospheric influence, and when a gale blows direct on the oven doors it is impossible to prevent some penetration of air, leading to combustion of gas inside the oven which destroys illuminants and increases the nitrogen content. The uplift caused by the column of hot material in the oven induces a suction upon the lower part of the oven even if considerable pressure exists in the gas space on the oven top.

Under the conditions of this separation of the gases the suitability of coke-oven gas for town supply has been proved by the arrangement which was carried through between Sir B. Samuelson and Co. and the Middlesbrough authorities. Since October, 1914, practically the whole gas supply of the town of Middlesbrough has been coke-oven gas. The average daily supply runs about 2,000,000 cb. ft., and no manufacture of ordinary gas has taken place since 1915. Shortages in the supply from the coke-ovens are made good by the manufacture of carburetted water-gas during the periods when town requirements exceed the oven supply. There has been no serious hitch in this undertaking, and its success has been assisted by harmonious co-operation of the representatives of the firm with those of the municipal gas authority. The public of Middlesbrough have obtained considerable financial benefit from this supply of gas, because, in the first instance, they could buy the gas cheaper than they could manufacture gas of equal quality, and they have not been called upon to pay an increased price due to the rise in price of coal. To-day this gas, with a selling price approx. 2s. 4d. per 1000 cb. ft. net, compares very favourably with any fuel for heating and cooking. The Gas Engineer informs me that its use has extended until the demand for cooking at meal hours exceeds that in lighting hours. This must be of importance in its influence in reducing distribution costs etc.

The author advocates that in all places where it can be adopted the regenerative coke-oven producing metallurgical coke is from a thermal point of view the most efficient means for gas manufacture, and that, compared with ordinary gasworks returns as published, if it can be adopted, it can supply cheaper and better gas to the town consumer at prices nearer the true thermal value.

I am indebted to Messrs. Dorman, Long and Co., Ltd., and Sir B. Samuelson and Co., Ltd., for permission to place this paper before you.

DISCUSSION.

Mr. T. HARDIE said that the results obtained by his firm in pre-war days did not correspond with

the figures given by Mr. Wright. Their returns from coke and breeze sales were nearer 55 than 45, and from other residuals nearer 28 than 24. In modern gas works it was possible to recover the waste heat not only from the settings, but from the coke itself, and the efficiency of such a plant was probably as great as that of any coke-oven plant, where much heat was lost in the discharge of coke. Coke ovens might have some advantage as regards handling large quantities of materials, but by modern mechanical handling methods that difference was considerably reduced as between gas and coke works. The use of coke-oven gas at Middlesbrough had been very successful, but he believed that a plant for the manufacture of gas had to be maintained there to supply gas in the event of the coke-oven supply failing. That plant had been put into operation fairly recently.

Mr. WRIGHT said that it was easy to understand that profits on coke and residuals at Newcastle were higher than they would be in the South or Midlands. The current price of gas in Middlesbrough was 2s. 4d. per thousand ch. ft., and he knew of no gas plant selling at less than that. The auxiliary gas plant had been erected because the coke-oven output was too small to deal with the increased demand.

On Tuesday evening the Lord Mayor gave a Civic Reception to the members at the Laing Art Gallery.

Wednesday, July 14.

A conference was held at Armstrong College on Wednesday morning, at which Prof. Henry Louis presided.

Dr. E. F. Armstrong, F.R.S., and Mr. T. P. Hilditch gave an interesting paper on "Catalytic Chemical Reactions and the Law of Mass Action," in which they described some of their recent work on the subject (see Proc. Roy. Soc., 1919, 96A, 322; 1920, 97A, 259, 265; also J., 1920, 120r).

SOME PROPERTIES OF 60:40 BRASS.*

BY CECIL H. DESCH.

The brasses used in engineering may be divided into two main groups, one of which is typically represented by the alloy containing 70% of copper and 30% of zinc, often known as cartridge brass, and the other by the 60:40 alloy. Alloys of the former class are composed of a single homogeneous solid solution, the α -constituent, and their most valuable characteristic is their great ductility, enabling them to undergo severe cold-working without cracking. On the other hand, the typical alloys of this class cannot be rolled at a red heat without great difficulty. The second class includes alloys with a duplex structure, the α -constituent of cartridge brass being accompanied by a second or β solid solution. The proportion of β increases from zero to unity as the percentage of zinc is increased from 36.5 to 46.5. This constituent has the property of being very plastic at high temperatures. Moreover, the ratio of β to α increases with the temperature, the normal ratio being restored on sufficiently slow cooling to the ordinary temperature. This property of plasticity makes it possible to shape the alloys which have a duplex structure by rolling, hot stamping, or extruding at or above a red heat, and rolled or extruded bars find many applications in engineering workshops. When cold such bars are readily machined.

In the course of using very large quantities of brass of approximately 60:40 composition in processes which involved many turning and drilling operations on automatic lathes, it was found that rods supplied by different manufacturers gave

widely differing results in the machine shops. In one instance a change from one brand of brass to another, nominally of the same character and composition, led to a drop of 40% in the output from the automatic lathes, whilst at the same time the wear on the tools was so greatly increased as to reduce their average life to one-fourth of its former value. The present investigation was undertaken with the object of throwing some light on the cause of such remarkable differences. A selection from the results has been made, and the present paper contains data relating to rods from sixteen different manufacturers. The experiments were mostly carried out in the Metallurgical Laboratory of the University of Glasgow, a few additional experiments having been made after removal to the University of Sheffield. I have much pleasure in expressing my indebtedness to Messrs. Wm. Cubitt and Co., London, to my father, Mr. H. T. Desch, and to Mr. Alex. Wylie, late of the Ministry of Munitions, for most of the material used in the investigation, and to Mr. A. N. McQuistan, of Messrs. R. Maclaren and Co., Glasgow, for permission to make experiments in the extrusion of trial mixtures in the works of that firm.

The composition of brass of this class always departs more or less from the nominal standard of 60% copper and 40% zinc, owing to accidental variations in the manufacture and to the presence of small quantities of other metals. A certain amount of lead is almost invariably added, with the object of improving the machining qualities; iron is usually present as an impurity; manganese or aluminium is frequently added as a deoxidiser when casting; and tin or nickel is sometimes added with the object of increasing the strength of the alloy. The rather high percentage of some of these metals in a few cases is no doubt to be attributed to the use of scrap in making the billets from which the bars have been rolled or extruded. The composition of the alloys used is given in Table I, the numbers in the first column being laboratory numbers, which are repeated throughout for reference. It should be stated that the zinc in all the analyses has been determined by difference. A few bars of exceptional composition have been included, as they were supplied to meet the same specification as the remainder, and they indicate the variations which are liable to occur in the supplies of metals which are nominally of the same composition.

When the proportion of one of the metals mentioned above does not exceed a certain limit it does not alter the essential characteristics of the $\alpha\beta$ brass, but is taken into solid solution, chiefly in the β constituent. When a larger proportion is present a third constituent makes its appearance, but no such separation has been observed in any of the alloys examined in the course of the present investigation, showing that the limits of saturation of the solid solutions were not exceeded. An exception

* Read in abstract, in the absence of the author.

must be made in the case of lead, which is visible in minute isolated globules in those specimens which contain a high proportion of that metal. A certain influence is, however, exerted on the structure by the presence of these foreign metals, since each metal, in passing into solid solution, has the same effect as a definite quantity of zinc. The structure of a complex alloy of this class is therefore the same as that of a pure copper-zinc alloy containing a somewhat different percentage of zinc. For many purposes, it is desirable to know the composition of the pure alloy which is identical in structure with the alloy under examination. Coefficients of equivalence have been determined, 1% of tin, for example, having the same effect on the structure as 2% of zinc. The other equivalents are: Aluminium, 6; tin, 2; lead, 1; iron, 0.9; and manganese, 0.5.¹

Representing the coefficient of equivalence of an element by t , and its percentage in a given alloy by q , we may calculate the 'apparent' percentage of copper in the brass, that is, the percentage of copper which would be contained in a pure copper-zinc alloy of identical structure, by means of a formula

$$B' = \frac{(B + tq) 100}{A + B + tq}$$

where B' is the 'apparent' percentage of zinc, B the actual percentage of zinc, and A the actual percentage of copper in the alloy. Should the alloy contain more than one added metal, the value of tq is calculated separately for each, and the sum Σtq is inserted in the formula. The values so calculated have been inserted in the table. As an example of this it will be seen that No. 612, containing 44.04% of zinc, has almost exactly the same structure as No. 616, which only contains 40.09% of zinc, the percentages of apparent zinc being 44.6 and 44.8, the latter value being raised by the added metals, aluminium especially, on account of its high coefficient, having a very great influence. As might be expected from a consideration of the microscopic structure, the mechanical properties are found to correspond more closely with the apparent than with the actual zinc percentage.

The photo-micrographs which accompany this paper represent longitudinal sections from bars, mostly of 2.4 in. diameter. The sections have been etched with an acid solution of ferric chloride, so that the β constituent appears dark and the α light. The size of the β grains is determined by the conditions of cooling in the higher range of temperature, all these alloys being composed solely of β immediately after solidification, whilst the crystals of α separate at a lower temperature, and their arrangement is mainly determined by the conditions of temperature distribution during the process of extrusion or rolling. Whilst the differences of structure between different bars are often strongly marked, it has not been found possible to distinguish the products of one works or even of one manufacturing process from those of another, as equally great differences may be found between bars made from successive ingots in the same casting shop, or even, in certain cases, between bars successively extruded from the same ingot. In the process of extrusion, the temperature falls considerably during the passage of the bar through the die, and the difference between the temperature at which the front end of the bar issues from the press and that at which the last portion emerges may, when the speed of extrusion happens to be rather slow, amount to as much as 100° C. Microscopical examination then shows two widely differing structures in different parts of the same bar. The outer and inner portions of a bar at the same cross section may also differ considerably in size of grain, but it has been observed that

the most fibrous bars, such as No. 618, are practically uniform throughout their section. It may be said that bars from those makers who were most successful in meeting the requirements of the machine shop were the most uniform in structure, so that bars from different consignments showed very little variation.

There is at present no satisfactory test by means of which the machining quality of a brass may be determined other than that of the workshop, and this test is only conclusive when continued over a long time, and with a large quantity of metal, in order to eliminate accidental variations in the sharpness of the tools, etc. It is shown below that tests of hardness in the ordinary sense, as revealed by the Brinell or similar methods, are of no value in determining the hardness of a brass towards a cutting tool. It was therefore thought advisable to use a workshop tool under conditions which could be easily regulated, and for this purpose a drill was selected. The machine used was a vertical, belt-driven drilling machine, from which the feeding arrangement had been removed and replaced by a lever, to the end of which was attached a quadrant, carrying a weight by means of a cord. The depth of the hole to be drilled was fixed by means of a collar attached to the vertical spindle. The bar to be tested was marked with a centre punch and placed in the vice immediately under the drill. The lever was raised to a definite angle and the height adjusted. The drill was then started, and the time taken to drill a hole to a depth of 1 cm. was noted with a stop watch. Each test was repeated, the values so obtained being very concordant. Three series of tests were made, the first and third using a $\frac{1}{2}$ in. twist drill at a speed of 300 revs. per minute, and the second with a $\frac{3}{8}$ in. drill at a speed of 700 revs. Fifteen bars were tested in this way. The first series showed a general increase in the time of drilling with increasing zinc, but the points did not fall at all regularly about any curve. The second series, at the higher speed, gave still more irregular results, and this was found to be due to the rapid blunting of the tool. The bars containing a high proportion of the β constituent were conspicuously hard when tested at the high speed, Nos. 612, 616, and 623 taking more than ten times as long to drill as the softest bars. The order of hardness of a series of brasses in a machining test depends largely on the speed of drilling, the angle to which the drill is ground, and the condition of its edge. (These factors have been carefully investigated for the case of steel by A. Kessner.²) The fine-grained brasses gave uniformly the best results at a high speed, but the figures have not been included in the table.

In the third series of tests, reverting to the slower speed and larger drill, and using certain added precautions, the conditions were more favourable. Drilling was more rapid, and possible errors due to the blunting of the drill were eliminated by testing bar No. 618, which had proved to be the best, at the beginning, middle, and end of the series, identical figures being obtained in each case. The results are shown in Table 2 and are plotted in Fig. 1.

It will be seen from the figure that whilst no single curve can be drawn through the points, they group themselves, on the whole, into two sets, each lying near to a line which rises with increasing zinc content. In one of these sets the machining times are all above 35 secs. and in the other all below. The softer bars include the two cast specimens and five extruded bars. The harder set includes three rolled bars and three extruded bars, two of which were abnormally high in zinc and therefore contained an undue proportion of the relatively hard β constituent. The bars obtained by extrusion which have a normal structure fall into the softer group.

Fig. 1.

Remarkable differences in the appearance of the drillings were observed. Owing to the rapid blunting of the tool, the appearance of the drillings obtained at a high speed was less characteristic than in the other cases, but it was found that Nos. 611, 617, and 618, which have a fibrous structure, yielded long spiral drillings even at the higher speed. In the third series the longest spirals were given by Nos. 610 and 617. The cast alloy, No. 615, gave exceptionally light and feathery short drillings in all the tests that were made. The character of the drillings in the third series is shown in Table 3, the percentage of lead being also indicated, since the presence of lead is known to favour the formation of short drillings. The table shows that spirals are formed from the bars containing less than 1% of lead and short drillings from those which contain a larger proportion, the only exceptions being No. 612, which is high in zinc, and No. 622, the reason for which is not obvious.

It has been stated by several writers that the Brinell hardness of a brass is a satisfactory indication of its machining quality, and it was decided to test this point. No Brinell machine was available in the Glasgow laboratory at the time, so it was decided to employ the auto-punch method, which is known to give good results. A heavy Brown and Sharpe automatic centre punch was altered by removing the point and substituting an adapter holding a one-eighth inch bicycle ball. On holding the punch vertically against the specimen and pressing, a blow was delivered, and an impression was produced, the diameter of which could be measured under the microscope by means of an eye-piece micrometer. Four impressions were usually made on each part to be tested, each impression being then measured on two diameters at right angles, and the mean of the eight readings taken. The results are collected in Table 4. The hardness of

each bar was determined on a line about half-way between the centre and the circumference, and also on a transverse section, the portion near the centre

and that as near to the edge as could be tested without distortion being tested separately. The results obtained at the centres of the transverse sections were, on the whole, the most concordant, but on plotting against either the real or the apparent percentage of zinc, a definite relation could not be found. The majority of the points lie in such a way as to indicate increasing hardness with increasing zinc, but three points lie so far from the curve that the differences must be more than accidental, and one of these three is No. 618, which is undoubtedly the best of all to machine, but which gives the highest value for the hardness by the auto-punch method of all the bars examined in that series. On repeating the experiments at a later date with a lever Brinell machine, the soft brass 618 once more gave as high a reading as the hard brass 612, containing an excess of the β constituent.

Table 4 also contains the results of tests made in Sheffield on the same specimens, using a Swedish Brinell machine of the usual type. The results are quite similar to those previously obtained.

It has been stated that the Brinell hardness of a brass may be accepted as a measure of the hardness in machining.³ Plotting the machining times against the Brinell numbers, however, no such relation is found, and an examination of the data contained in Mr. Ellis's paper shows that the conclusion is unjustified. When the data in Table E, on p. 36 of that paper, are plotted they are found to be distributed in an apparently random fashion, so that no curve drawn amongst them has any justification. The writer is convinced that the Brinell hardness is unconnected with the machining quality of a 60:40 brass.

The process of scratching a metallic surface with a diamond or other hard point closely resembles that of cutting with a tool, and it was therefore thought that a useful test of hardness might be made by means of the sclerometer, an instrument long used for the determination of the hardness of minerals, and modified for application to metals by Prof. Turner.⁴ Finding that the usual construction of this instrument was insufficiently rigid, so that the arm carrying the diamond was liable to shake during the making of the scratch, producing a wavy line on such a tough metal as brass, an improved instrument was constructed, in which the light pivoted arm was replaced by a rigid rhombic frame, supported by two hardened steel conical pivots six inches apart, and balanced so as to swing freely. The specimen was supported on a carriage moving between parallel guides, having an elevating pillar to accommodate specimens of different sizes, and screw traversing motion allowing several parallel scratches to be made. Four scratches were made on each specimen under the same load, and the breadth of each scratch was then measured at two different points under the microscope, using a Ramsden eyepiece

micrometer. The surface of the specimen was always polished before testing.

The difficulty found in applying this method arises from its extreme delicacy. Duplex alloys, such as $\alpha\beta$ brass, show a scratch which is not uniform in breadth, but consists of a series of alternately broad and narrow portions, corresponding with the relatively soft α and hard β respectively. It is therefore necessary either to use a heavy load or to measure under so low a magnification as to obtain the average breadth. The results are shown in Table 5.

Plotting the measurements against the machining times, no definite relation is observed beyond the sharp separation into two groups, previously noticed. It is intended to continue this part of the investigation, as it would seem desirable to have a laboratory method which would enable the working hardness of a brass to be determined with speed and accuracy, and a sclerometric method appears to promise more than any other as yet available.

It is frequently reported by machine shop workers that a bar has a hard skin on the surface, which causes blunting of the tool at the first cut. Brinell and scleroscope measurements across a transverse section of a bar frequently, but by no means always, show an increase of hardness as the edge is approached. This is due in part to greater closeness of grain in the outer portions and in part to cold working. The writer has found no evidence of hard particles of oxide in the outer layers. The bars as received are usually remarkably free from oxide, and in the few cases in which oxide has been found it is of a light, powdery nature. Neither can the skin hardness be attributed to rapid cooling at the surface, retaining the brass in the hard β condition. On the contrary, the outer zone is always slightly richer in α than the interior, owing to a small loss of zinc during the processes of manufacture. Attempts have been made to determine the hardness of the original skin, both by Brinell and by sclerometric methods, but the results have been unsatisfactory, the surfaces of some of the bars being so rough that accurate measurements could not be made, whilst grinding or polishing the surface would have defeated the object of the experiment.

Two bars were received which had been pickled in acid in order to remove oxide. The machining tests did not indicate that the metal was appreciably softened thereby, and, in view of the evidence in the last paragraph, it is not to be expected that pickling would be of any great advantage.

Portions of some of the bars were annealed by heating for two hours in a muffle at 700° C., the specimens being packed in kaolin to avoid oxidation. They were then ground and polished, and tested by the auto-punch method. The effect on the structure was to coarsen it slightly and to cause rounding of the α crystals when these were previously angular. The diameter of the impressions is given in Table 6 and plotted in Fig. 2. The relation between the Brinell hardness and the per-

centage of apparent zinc is brought out clearly, the bars now being in a comparable condition.

Apparent percentage of zinc.

Fig. 2.

The influence of the structure on the machining quality of the brass is well illustrated by Nos. 351 and 352. It will be seen from Table 1 that the composition of these two specimens is practically identical, but workshop reports gave the former as soft, and the latter as hard, in the automatic lathes. The photo-micrographs, Figs. 3 and 4, show that the α crystals are arranged in the one case in an almost parallel fashion, giving a fine fibrous grain to the metal, whilst in the other they are coarsely angular. The difference of hardness in this case is to be attributed to differences in the treatment of the metal after casting. Figs. 3 and 8 illustrate the conclusion, which the writer has reached as the result of this investigation, that a fibrous structure is favourable to ease of machining. It is only necessary to compare the photographs with the records of the machining times in Table 2.

A few words may be said on the subject of variations from the normal 60:40 composition. It is the practice of some manufacturers to use a considerably larger proportion of zinc in billets intended for extrusion. The higher the zinc the more readily is the alloy extruded under the usual conditions of temperature. This procedure results in the production of a bar which is hard to machine. By far the best results are obtained from an alloy containing 40% of apparent zinc, whilst the true percentage should be only slightly less, the difference being made up by lead. The quantity of the latter metal may approach 2%, but 1.5% is probably sufficient in most cases. Tin, iron, and aluminium should be reduced to the lowest possible proportions. The best alloy in the whole series, as proved by workshop experience extending over many months, was the American brass, No. 618, and this was used as the standard of comparison throughout the experiments. It has the highest chemical purity of any of the specimens and contains exactly 40.0% of apparent zinc. One of the worst is No. 616, which contains the largest quantity of impurities.

Extreme variations are not doubt sometimes due to errors in weighing out the ingredients before melting. Two examples are seen in Nos. 694 and 712. The former consists of the α constituent, with only occasional traces of β , whilst the latter con-

tains so high a proportion of zinc that the β crystals are bordered by layers of the γ constituent, an exceedingly hard and brittle substance of a light-blue colour. Brasses which contain even a minute quantity of γ are excessively brittle and may be broken by a light blow. Such a composition is only to be attributed to accident.

A comparison of the results leads to the conclusion that an arrangement of fine, fibrous α crystals, separated by a comparatively small quantity of β , is the most desirable structure for machining purposes. This is obtained by employing an alloy containing as nearly as possible 40% of apparent zinc, and extruding at a moderate temperature. Such an alloy, however, flows less readily than one with a higher proportion of zinc, and powerful presses have to be used. Some experiments were made with a series of billets containing 60.5% of copper, and these were extruded in the ordinary way from a 600-ton press. The billets proved to be very hard and were liable to stick in the press, so that three of the bars produced were only of one-half the normal length, half of each billet being left in the press. The structure was quite satisfactory, being fine and fibrous. It was ascertained that the presses used by the American firm which produced the brass No. 618 were of much greater power. It would be possible to use the presses of lower power for the 60:40 alloy, but the temperature would have to be high, and the fine structure would not be obtained.

DISCUSSION.

Mr. O. SMALLEY said that in a similar investigation, an alloy containing Cu 59%, Pb 1.25%, Zn 39.75% had proved to be the most easily machined so far as composition was concerned. With regard to physical examination, this had been limited by the fact of all the bars used having been extruded in a comparatively low pressure machine; the temperature range necessary for successful extrusion had been in consequence somewhat high, 760°–780° C. The result of this had been that the front portion of each bar had possessed a coarse angular structure and the back end the fine fibrous $\alpha\beta$ structure favoured by Dr. Desch. In view of this difference of microstructure, it had been of little use proceeding with the investigation on the lines taken by Dr. Desch, although experiments had been made to ascertain if any difference could be detected in the machining qualities of the front and rear ends of various bars, but with no result. During this investigation experiments had been conducted on the effect of cold work on 60/40 brass, and it had been found that the above-mentioned brass cold drawn 0.02–0.05 in. met all requirements, and machined as easily as the American bars which had been set as standard. The effect of this cold work on the physical properties of the brass was to increase the elastic limit 7–10 tons and the maximum stress 3–4 tons per sq. inch; structurally no change had occurred, the cold work penetrating uniformly to the centre of the bar. Subsequent to the completion of this investigation the workmen in one of the shell shops "downed tools" because of the difficulty in machining copper driving bands. Examination of these bands had shown that they had been made from pure copper containing 0.1–0.18% oxygen as cuprous oxide, and that they had been seriously over-annealed. By reducing the number of annealings in the cold drawing of the bands and finally annealing at 600° C., the elastic limit had been reached without materially affecting the tenacity or hardness. The bands had proved satisfactory and had met all requirements so far as machining was concerned. Later arsenical copper driving bands had been used. These had been found to machine satisfactorily, irrespective of the final annealing temperature. The effect of the arsenic (0.25–0.35%) was to raise the elastic limit without

materially influencing the other physical properties.

In view of these results he could only conclude that the elastic condition of the 60/40 brass was of more importance than the structural disposition of the microconstituents, as suggested by Dr. Desch.

CHEMICAL SHEET LEAD.

BY D. W. JONES.

Chemical lead is referred to by Percy ("Metallurgy of Lead") as follows:—"The purest lead, i.e., the softest, is stated to have been found best for sulphuric acid chambers, but . . . soft lead obtained direct from good ores is more durable . . . for such chambers than soft desilverised lead." Analyses are not given, and the probable reason for this observation will be referred to later. Lunge ("Sulphuric Acid and Alkali") quotes opinions, some of which incline to the belief that lead is the more acted upon (by sulphuric acid) the purer it is, whilst other opinions favour a lead containing small quantities of antimony and copper in order to make it more resistant. His own conclusion, arrived at after much work upon the subject is, that "at higher temperatures the purest lead resists both pure and nitrous sulphuric acid much better than regulus metal or hard lead." More recently Barrs (J., 1919, 407 T) has found an increase in purity in lead to correspond with an increase in the power of resisting attack by acid, but recommends the addition of 0.02–0.05% of copper to ensure obtaining the maximum resistance.

It is in the manufacture of and processes using sulphuric acid that the largest quantity of chemical lead is required, and, generally speaking, the property of resistance to attack by this acid which a lead may possess is a measure of its resistance to attack by other acids.

The quantity of lead required during the war for the above purposes exceeded by far any previous demands, and it was during this period that the following work was undertaken.

To determine the quality of chemical lead it is customary to make examinations by all or any of the following methods:—

(1) Heat in 96% sulphuric acid up to 290° C. in five minutes, cool to 100° C., and observe loss in weight.

(2) Heat in 91–92% nitric acid. No appreciable action should occur in fifteen minutes.

(3) Heat in a mixture of 40% of nitric acid, 52% of sulphuric acid, and 8% of water. No appreciable action should take place between 93° and 109° C.

(4) Heat a filed surface in a mixture of one vol. of hydrochloric acid, sp. gr. 1.14, 2 vols. of nitric acid, sp. gr. 1.50, and 3 vols. of water. The time required for spots of lead chloride to appear, and the time at which vigorous action takes place after boiling, are noted.

(5) Heat in concentrated sulphuric acid and observe the temperatures at which bubbles of gas are first evolved and at which the lead decomposes.

Of these methods No. 5 is the one most generally favoured. When under observation by this method in some cases the decomposition of lead is sudden, total, and violent, and is attended by a rise of temperature after removing the source of heat up to 27° C. With a good quality lead decomposition proceeds slowly, and is arrested when the source of heat is removed. The temperature recorded is that at which the solution becomes slightly turbid owing to the formation of lead sulphate. Since it has been found that 96% sulphuric acid (by wt.) gives figures comparable with those obtained when chamber acid is used, all observations refer to trials conducted with pure acid of this concentration.

The tests to be described were carried out under the following conditions:—A test piece of rolled lead 1 sq. in. in area and $\frac{1}{8}$ in. thick (corresponding

approximately to sheet 4 lb. per sq. ft.) is heated with 30 c.c. of 96% sulphuric acid at such a rate that the temperature of the acid reaches 300° C. in five minutes.

A suitable chemical lead when tested in this way evolves bubbles of gas at 190°—200° C. and decomposes at 300°—312° C.

pared from Parkes lead on a commercial scale by a process which is the subject of a patent granted to my firm in 1920. It contained Cu 0.0009% Bi 0.0007, Fe 0.0003, Ag 0.0005, Sb 0.0002, Zn 0.0019, Sn, As, Cd, Ni, Co nil, Mn traces, Pb (by diff.) 99.9955%. The results of these additions are shown in the following table:—

Behaviour of chemical lead when heated in sulphuric acid.

† With 0.04% Bi and 0.005% Sb a=199°, b=270°; with 0.04% Bi and 0.01% Sb a=198°, b=238°C.

Remarks.—With the original metal, and also when copper was added, partial decomposition occurred, the action soon ceasing when the source of heat was removed. With 0.005% Sb total decomposition was observed, lead sulphate being formed at 270°C.; with higher percentages total and violent decomposition occurred. With Cu and Sb there was partial decomposition, with indication of lead sulphate about 10° below decomposition point. With zinc partial decomposition occurred; no indication of lead sulphate except with 0.02% and 0.05%. With phosphorus and mercury, total decomposition was observed. With tin, partial decomposition occurred, with slight indication of sulphate at 260°C. With 0.005% and 0.01% Bi decomposition was partial, with 0.02—0.04% total, and 0.05—0.06% sudden, total and violent. With 0.005% Bi and Sb decomposition was partial, with 0.01% total, and with 0.02% more sudden, violent, and total.

The following figures have been obtained from the examination of many hundreds of samples of lead refined by the Parkes process, including English, Spanish, Australian, and American supplies:—Bubbles of gas evolved: average 187° C.; maximum, 212°; minimum, 146°. Lead decomposes: average 235°; max., 280°; min., 183° C.

Thus Parkes lead without further treatment is unsuitable for use in many operations. To test the effect of impurities on the chemical properties of lead additions of pure metal were made to a Parkes lead containing Cu 0.003%, Bi 0.007, Fe 0.0018, Ag 0.0005, Sb 0.006, Zn 0.0018, Sn, Ni, Co, nil, As, Mn, traces, Pb (by diff.) 99.9799%. The results of these additions are shown in the following table:—

With copper and with copper and antimony together, and also with sodium, partial decomposition occurred. At 0.06% Cu and Sb local action was observed, streams of lead sulphate being formed which dissolved 20° below the recorded decomposition temperature. With mercury total decomposition occurred.

It is of interest to note how the addition of a number of elements affects the resistance to attack by sulphuric acid upon a lead known to possess this property. For this purpose the lead used was pre-

This work has been confined to the addition of comparatively small amounts of impurities, many of which are known to exist in commercial lead, with the object of devising methods of eliminating those impurities found to possess a deleterious effect.

From the above tables it is evident that the presence of antimony in lead to the extent of 0.01% renders it unfit for use in the manufacture of chemical plant.

With 0.06% of added antimony the temperature of initial attack is restored, but as this amount is never found in commercial lead (which is usually of a purity of 99.98%) and it is not conceivable that an addition of 0.06% antimony would materially lead to additional strength, there can be little or no advantage derived from the fact.

Hard lead sheet and pipe containing 0.75—5.25% Sb in no case gave a higher decomposition temperature than 244° C., but at temperatures above 220° C. signs of gas bubbles are first observed when this type of lead is heated in concentrated sulphuric acid.

Antimony, therefore, if present in lead in practically any proportion above the most minute, will, in the absence of a known corrective agent, be the cause of immediate breakdown if temperatures much over 200° C. are employed.

Copper also has a marked effect in reducing the temperature of initial attack by sulphuric acid. The figures in the tables point to the fact that there is a danger zone lying beyond 0.03% in lead of the Parkes type, and in the "chemical" lead clearly defined between 0.03 and 0.045%. If copper be introduced, due consideration must be given to the above-mentioned factors.

The effect upon the decomposition temperature of the addition of copper upon a Parkes lead is most beneficial; 0.005% introduced shows a rise of as much as 23° C., and at the same time is sufficient to prevent the vigorous action which causes the whole of the lead to be converted into sulphate and consequent total destruction. The gain achieved by introducing 0.03% is 37° C., and brings an ordinary lead within measurable distance of chemical lead. No remarkable effect ensues from the addition of copper to a pure chemical lead; a gain of 4° C. at 0.04% addition is all that calls for comment.

Most probably the reason for the statement previously quoted from Percy is that the soft lead derived from pure ores contained about 0.01 % Cu; similar lead to-day approximates to that amount and compares very nearly in all respects with Parkes lead when 0.01 % Cu has been added. Such lead may have been more resistant to acid than desilverised lead manufactured at that period, especially when it is remembered that pan concentration of sulphuric acid was more universally in use. Lange ("Sulphuric Acid and Alkali") at a later date has stated:—"Hence the purest lead is subject to instantaneous solution by sulphuric acid at 260° C." Pure lead is, however, manufactured to-day which withstands the action of hot concentrated sulphuric acid without being instantaneously dissolved when heated beyond 300° C.

The effect of copper in counteracting the harmful influence of antimony in lead is evident from the tables. In no case is total decomposition brought about, which, with antimony only present to the same extent, would result in every instance. With between 0.02 and 0.03 % of antimony and copper there seems to be a rise in the temperature of initial attack; this fact may be of some value if lead containing these amounts of antimony and copper is used for purposes dealing with concentrated acid at comparatively low temperatures.

Zinc, when present in lead even in very small amounts, is generally supposed to destroy the power to withstand the corrosive action of acid in a marked degree; this is not borne out by any work undertaken by the author, which embraces the examination of chemical lead prepared by different methods to which additions of zinc have been made. The temperature at which the first action is discernible is lowered in all cases. At 0.02 and 0.05 % a degradation of resistivity is evidenced by the formation of lead sulphate much below the temperature of complete solution. At 0.03—0.04 % Zn a critical stage exists where this injurious effect is not operative.

Mercury when alloyed with lead has a deleterious effect upon its "chemical" properties. By amalgamation this effect is more serious. If 1 % of mercury is rubbed over the surface of a piece of chemical lead until amalgamation appears to be completed, allowing one hour as contact time, the product is very sensitive to the action of hot concentrated sulphuric acid. At 170° C. lead sulphate is formed copiously. If the heating be discontinued at this stage the action of the acid will cease on cooling to 70° C. After washing the lead sulphate from the trial piece it will be observed that pitting has proceeded over the entire surface, and minute globules of mercury can be seen under the microscope. If this piece of lead be again heated with sulphuric acid action will commence at 180° C., and sudden, total, and violent decomposition will take place at 220° C. Repeating the above, but allowing contact overnight between the lead and mercury for more complete amalgamation, a distinct action is noticeable on heating to 50° C. At 100° C. total decomposition accompanied by the usual phenomena takes place. Using 0.1 % of mercury on the weight of lead of standard size (i.e., just sufficient to cover one-third of the area), and allowing two hours for amalgamation, a distinct vigorous action commences at 100° C., and total solution takes place at 215° C.

These observations indicate that great care must be exercised when using hydrometers etc., for if these instruments are broken and the mercury permitted to amalgamate with the lead, local action in the affected part, followed by a breakdown, can be expected.

Tin has a degrading influence upon lead intended for chemical purposes, though not to the extent generally believed. Since it is easily removed by

refining methods of to-day, it is not usually found in lead in more than minute traces.

Bismuth, so frequently associated with lead of American origin, is decidedly injurious if present above 0.01 %, and even at 0.02 % it causes total decomposition in an otherwise resistant lead. The addition of 0.02 % of copper to lead containing 0.05 % bismuth will be sufficient to raise the temperature of decomposition from 273° to over 300° C.

The combined effect of antimony and bismuth is noteworthy. The addition of 0.005 % of each metal leaves chemical lead practically unaltered, but when 0.02 % antimony and 0.02 % bismuth are present there is a difference of only 12° C. between the temperatures of first action and of violent decomposition.

Doubtless the poor chemical quality of Parkes lead in some instances is due to its containing antimony and bismuth in some peculiar proportion, as singly their effect when added to a pure lead is not so pronounced.

Investigating the cause of the breakdown of lead concentrating pans, Hart (J., 1907, 504) stated that 200° C. is never exceeded in this class of work, and that the trouble occurs when the acid has reached a sp. gr. of 1.65—1.675, and may occur at sp. gr. 1.63 after constant use for a long period. A possible explanation of these defects might lie in the peculiar behaviour of pure lead to which antimony and bismuth have been added. Though these metals may not originally be present in lead in the exact proportion which leads to decomposition at or even below 200° C., a selective action of sulphuric acid upon lead known to contain bismuth and antimony may ultimately bring about conditions resulting in breakdown in pan concentration.

A practical method favoured by acid manufacturers of testing lead intended for chambers is to expose sheet, previously weighed and measured, to the exit gases of a No. 1 chamber (the gases at this point are considered most corrosive) and note the loss per unit of area exposed over a given period, usually not less than three months.

The following are the details of a trial, as described, upon four different samples of sheet lead exposed to the action of chamber gases for 130 days:—

Description.	Behaviour when heated in sulphuric acid.		Area sq. in.	Loss per sq. in. gms.
	Gas evolved °C.	Lead decomposes °C.		
Pattinson lead	200	316	19.500	1.274
Do. + 0.38 % Cu	215	325	19.132	1.323
Pattinson lead (old sheet from the side of a No. 4 chamber)	210	300	26.800	0.749
Chemical lead prepared from Parkes lead	202	314	19.750	1.254

The behaviour of sheet lead which had seen previous service is remarkable; this had a fine coating of lead sulphate on its surface, which was not removed before beginning the trial. It is possible that, not being an immersion test, a protective action is exercised by this coating of lead sulphate. Apart from this result pure lead shows the smallest loss, and a Pattinson lead shows a smaller loss than the same lead to which copper has been added.

Assuming the loss of pure lead to be unity, and that lead of 7 lb. per sq. ft. is under consideration, the increased loss suffered by Pattinson lead in chamber work as compared with pure lead would be 5.7 lb. per ton of lead per annum, and for Pattinson lead containing 0.38 % added copper 19.6 lb. per ton per annum.

Of the whole of the elements used for additive purposes, there are only two which consistently

exert a beneficial influence upon the chemical properties of lead, *viz.*, copper and sodium; this is most marked with non-chemical lead, and in the case of copper does not apply to any extent to additions made to a pure chemical lead. Avoiding those quantities which produce a fall in the temperature at which the first action is discernible, something may be said in favour of lead containing copper on account of a gain in strength and rigidity thereby secured. It is by fatigue, produced by constant use above normal temperature, that lead often becomes unreliable; here again the introduction of copper should prove advantageous.

Of other additions it may be said that they are injurious in their effect, though in most cases not to the extent generally supposed. There is one outstanding instance, *viz.*, antimony, which, if present in lead in quantities which a commercial metal may contain, will effectively debar its use as "chemical" lead.

Chemical lead is sometimes subject to local action, attributed to oxides which in places become rolled out into the sheet. By a careful control of casting temperature alone this source of danger can be largely eliminated. Lunge gives the oxygen content of pure lead as 0.0024%; with antimony and copper present the oxygen can be as high as 0.005%. This again is advanced as an argument in favour of the use of pure lead for chemical purposes.

Reference to the table (page 222 r) will show that local action is most pronounced when copper and antimony are together present in lead.

In spite of the fact that copper can function as a corrective agent and will counteract the injurious effect of antimony and bismuth in lead, the author is yet in agreement with Rhead (see J., 1920, 128 r), who has emphasised the importance of using pure lead in connection with acid plant.

In conclusion, my thanks are due to Messrs. Locke, Blackett and Co., Ltd., for permission to publish this work.

DISCUSSION.

Dr. WEYMAN asked to what extent the impurities were introduced into lead after it had been put into use. It was conceivable that lead used for lining iron vessels might become contaminated with iron.

Mr. R. T. HARRISON thought that nearly all impurities in lead came out of solution when the lead was cooled. It had been shown that by immersing lead in acetic acid the impurities were dissolved out and brittle lead was produced.

Mr. H. DUNFORD SMITH said that he could confirm nearly everything the author had stated. He rather doubted, however, whether the test with sulphuric acid was representative of the conditions in the chamber itself. The author had cited four instances of lead being hung in the exit of No. 1 chamber in which he had shown that old lead which had previously been used in the chamber underwent less corrosion and loss of weight than even his own pure lead which he placed in the highest position. It seemed to him, therefore, that while the test was very useful for sorting out the good leads from poor leads, it did not differentiate between the different degrees of the better class leads. He (the speaker) had made tests of lead containing copper in chambers which had shown up much better than many pure leads. If Mr. Jones could in some way correlate his tests with actual practice it would be of great value.

Dr. FLECK suggested that the beneficial effect of sodium might be due to the fact that it reduced the quantities of oxide present.

Mr. JONES, in reply, said that he had made no chemical tests of the lead lining of iron tanks, but he had had experience with the use of a tank lined with lead to dissolve sodium sulphide in river water; that tank had been in use for five years and

had required no attention. He thought that with a good lead there need be no fear of contamination from an iron tank. His experience indicated that the addition, say of 5%, of copper to crude lead would inhibit atmospheric corrosion. When sodium was added to lead there seemed to be evidence of reduction, and Dr. Fleck's theory was probably correct.

The CHAIRMAN said that the paper had been interesting to him as showing how the work of his old teacher, Dr. Percy, had stood the test of time. He was wonderfully accurate in spite of the difficulties of the early days in which he worked.

Mr. H. C. LANCASTER writes:—

"I should be interested to hear if the author has satisfied himself that the pure metals added to test the effect of impurities were actually present in the final lead in the same proportions as when added. I have proved conclusively that it is difficult even to get 50% of the added copper to be retained by lead, although it is a very simple matter to get retained almost a true equivalent of antimony and the other metals of low melting point. The author refers to a Pattinson lead containing 0.38% of added copper. My experience has proved conclusively that a chemical lead, and certainly a Pattinson lead, will not retain 0.38% of added copper. For instance, I have found that at the necessary temperature pure chemical lead dissolves quite easily 0.5% of added copper, but when the lead is afterwards melted and poured into a mould the resulting lead contained only 0.15% Cu, showing that this copper has a great tendency to liquefy out at comparatively low temperatures, and this is, of course, a condition always present when manufacturing sheet lead. In my opinion, it is impossible under normal conditions to produce a sheet lead containing 0.38% of copper, especially if the lead is otherwise very pure, although impurities do tend to keep copper in a lead, especially in the presence of arsenic and antimony."

RECENT DEVELOPMENTS OF THE ELECTRIC FURNACE IN GREAT BRITAIN.

BY D. F. CAMPBELL, M.A., A.R.S.M.

In no branch of metallurgy have greater advances been made during the war than in the development of iron and its alloys, which has given us materials of extraordinary strength and physical properties. Steel for aero engine parts owe their power and lightness to the addition of small percentages of metals, aeroplane wire its strength and bullet-proof steel its toughness to the addition of suitable alloys, such as those of nickel, chromium, molybdenum, or manganese, and the electric furnace has been responsible in most cases for both the reduction of these refractory metals from their ores and the subsequent manufacture of the alloy steels for these special purposes.

Newcastle has been the principle centre for the reduction of chromium, tungsten, and molybdenum ores, and at the time of the Armistice works were in regular operation of sufficient capacity to produce Britain's war requirements of these essential metals.

In 1914 the quantity of energy used on electric furnaces in Britain, excluding those used for aluminium, was probably less than 6000 h.p., but on the day of the Armistice the total capacity was in excess of 150,000 h.p., of which 135,000 h.p. was producing steel, and 18,000 h.p. was working on the reduction of chromium and tungsten ores. On the day of the Armistice electric energy was being consumed at the rate of nearly 300,000,000 kw.-hrs. per annum for furnace work alone. The electric steel production had then reached a total of over 200,000 tons per annum.

Similar progress has also been made in the electrolysis of brine for the manufacture of caustic soda

and chlorine to meet war requirements, and the older processes are now superseded by the electric method of manufacture.

The manufacture of large quantities of phosphorus by electric-furnace methods was necessary during the war, and the excellent fused silica wares for laboratories and chemical works, made with such remarkable success on the Tyne, is perhaps the most interesting example of the use of the electric furnace for fine work.

The making of large electrodes, an essential subsidiary industry for electric furnace work which was unknown in Great Britain in 1914, is now established in Newcastle and elsewhere, and also the manufacture of artificial graphite in the form of electrodes for furnace work and electrolysis and powder for accumulators and similar purposes.

But the main interest lies in the reasons for the extraordinary development of electric furnaces and the technical advances which have been made.

Electric melting enabled us to use advantageously the vast quantities of steel turnings made in the shell factories, and the continuous traffic of lorries removing turnings direct from the lathes to the furnaces of Sheffield soon disposed of the vast accumulations of rusting material which were so commonly seen in the early years of the war.

The re-melting of nickel-chrome steel is a wasteful and most difficult process in all other furnaces, but the reducing conditions and absolute control of the electric furnace make it possible either to retain or remove at will most of the chromium, and thus large quantities of a valuable metal were saved.

The economic manufacture of stainless steel has been rendered possible only by the electric furnace, which is required both for the preparation of the refined ferro-chrome and the steel melting. This remarkable steel, containing 13% of chromium and a low percentage of carbon, will surely have a wide range of usefulness in engineering as well as in domestic fields. Its properties of resisting vegetable acids and corrosion from many other causes has made it a most valuable substance for valves, hydraulic equipment, and other engine parts. It can only be made by the use of ferro-chrome containing a very low percentage of carbon, and the preparation of this metal presents very serious difficulties. These have, however, been completely overcome in this district, the ore from India, Rhodesia, or New Caledonia being reduced and subsequently decarbonised to the required extent in electric furnaces.

The application of electricity to metallurgy has given us the low-hysteresis iron that is now universally used in transformers, for this is made by the addition of high-grade ferro-silicon to the steel. A gain of $\frac{1}{3}$ % in efficiency on a single transformation of the thousands of millions of units generated annually in Great Britain is equivalent to saving scores of thousands of tons of coal per annum. This material is still capable of improvement, and it is hoped that extensive research will be undertaken forthwith.

The use of the arc furnace in one of its many forms is now almost universal, and the fascinating principle of induction heating is no longer used. Electric furnaces owe their value to their intense reducing conditions, as they utilise the only practical source of heat which does not require oxygen for its generation. The furnace may be a closed box, e.g. when used for the reduction and volatilisation of phosphorus or for the final deoxidation of steel. Another fundamental advantage of arc furnaces is due to the fact that the slag is necessarily hotter than the steel, and the refining action takes place at the surface of contact between the slag and the steel, whereas with induction the slag was always cold and refining practically impossible.

The tendency in electric furnace design is rather to increase the power of transformers on furnaces of moderate capacity than to build large furnaces.

One limiting factor is the size of electrodes that can be conveniently employed; but if there were any demand for larger furnaces, there is no objection to the use of six or more electrodes.

Where large tonnages of electrically-refined steel are wanted, it is customary to refine steel previously melted and treated by the Bessemer or Thomas process, and in that case the electric furnace need never be of more than 25 tons capacity, which is the largest vessel used for these processes.

There are technical disadvantages in electric furnaces of more than 25 tons or more than 3000 kw. capacity, and there is no great advantage in using the furnaces of 6000–7000 kw. which have been recommended abroad for making alloys and carbide.

In most furnaces of the arc type, regulation of load is effected by variation of the arc gap, either by hand or automatic regulation. The latter system has probably been more highly developed in this than in any other country, owing to the high cost of power, and the system by which individual furnaces are kept at any desired constant load by Thury automatic regulators is widely applied. The regulation also materially assists in keeping both the composition of the bath and temperature of the furnace within desired limits. In addition, the regulation of a battery of furnaces by a master instrument is of especial interest to power producers and those who pay for energy on a maximum-demand basis. An instrument is finding application which will keep the total load of a battery of furnaces within desired limits by slightly reducing the load on the furnaces if the demand at any time exceeds the total load which the station engineer or the power contract may set as a maximum total load to be utilised. Individual furnaces can be removed from the influence of the master regulator by drawing a switch, but the energy absorbed by that furnace is always included in the total power which the regulator will allow the furnaces to absorb.

The lack of understanding between the power consumer and energy producer often leaves much to be desired, and greater efforts should be made to realise the difficulties and requirements of the two undertakings, which are so entirely interdependent, if electro-metallurgical industries are to succeed.

The preparation of contracts for supply requires the most careful consideration by engineers who have experience both of power generating and also of electro-metallurgy, if harmonious working is to result.

The development of electrical energy on the North-East coast is undoubtedly the most progressive and comprehensive system in Great Britain, and it is hoped that the development of other districts will result in schemes for linking up existing supplies, exchange of surplus capacity with a general reduction of stand-by plant, and the erection of a few large stations at suitable points, so that the small and inefficient stations may be abandoned or relegated to the position of emergency stand-by plant.

There are great advantages in establishing certain electro-metallurgical processes in England in spite of the lack of water power, for this country is so highly favoured with the other essentials for successful industry that the supposed advantages of cheap hydro-electric energy are counterbalanced in the case of many processes in which skill and cheap raw materials are an important factor; consequently power economically generated from steam and efficiently distributed may form the basis of many electro-chemical industries.

Coal-generated power is constantly available, whereas water-power is only too often subject to great seasonal variations. Seasonal labour and variation of output all tend to raise the cost of production. Consequently, only few industries, comparatively easy of accomplishment and requir-

ing large energy consumption, flourish in the centres where water power is available.

The production of aluminium, ferro-silicon, and carbide are industries for which water power is usually essential, but in steel-making the quantity of energy used is comparatively small, and the skill and special plant required for its treatment are so great, that the local advantages of England outweigh the advantages of low power cost abroad.

Processes such as steel-making that only use about 40% load factor, i.e., four-tenths of the possible output of the plant reserved for their use, are more suitable for steam stations, which have low capital expenditure and high running costs, rather than hydro-electric stations, which involve the outlay of large sums for capital account, but small operating expenses.

The utility of the electric furnace did not cease on the day of the Armistice. Shops equipped with electric furnaces for war alloys have been reconstructed and are producing alloy steels. The manufacture of artificial graphite, a new industry to this country, has been established, and electrodes of a size and quality equal to the best in the world are being produced, and the manufacture of alloys and amorphous electrodes is being developed along the lines of present requirements.

The next immediate development will probably be the general application of electric smelting to the treatment of complex zinc ores and the gradual improvement of existing processes in the development of power and utilisation of the fuel we now waste.

Electro-metallurgy is still in its infancy, but its growth is rapid. Abroad generating stations of 100,000 h.p. are being used in some cases for single industries, and electro-metallurgical centres absorbing several hundred thousand horse-power are being developed in various countries, while many similar projects are under consideration.

Agriculture, the greatest of all industries, requires that nitrogen be rendered available for the growth of plants, and the whole problem of artificial fertilisers and the influence of electric discharge in agriculture affords an intensely interesting subject for research.

The rapid growth in the world's consumption of aluminium and the great possibilities of its alloys offer a fruitful field for investigation and industrial enterprise.

Improvements in the metallurgy of steel, and the study of alloy steels in particular, have enabled engineers to produce the aeroplane, and will doubtless lead to lighter and stronger structures, such as bridges, locomotives, and ships, with a corresponding reduction in weight and increase in efficiency.

Peace is demanding new products and extraordinary opportunities are apparent on every side for maintaining the supremacy of science and engineering which we established during the war.

DISCUSSION.

Mr. A. G. LOBLEY said that electrodes for aluminium furnaces had been made in this country ever since aluminium had been made here. Moreover, both the companies making aluminium in this country could produce a better electrode than was produced abroad for the purpose. No reference had been made to the resistance type of furnace. At least one furnace of that type was working now on a large scale. The development of the resistance type had presented many difficulties, but he had now overcome these, and a furnace was running efficiently in the hands of workmen without any electrical knowledge. The type had the advantages of clean working and general efficiency.

CHEMICAL ENGINEERING GROUP.

CONFERENCE ON FILTRATION.

On Tuesday afternoon and Wednesday morning the Chemical Engineering Group held a conference on Filtration, at which a number of papers were read and discussed. The full papers, with discussion, will be published later in the Proceedings of the Group.

Some of the papers are given below in abridged form.

THE PRINCIPLES OF TECHNICAL FILTRATION.

BY EMIL HATSCHEK.

Filtration in the accepted sense of the term is generally defined as the separation of liquids from solid particles of microscopic size suspended in them, by means of a porous septum which allows the liquid to pass but retains the particles. The definition is somewhat narrow, as, on the one hand, it has been shown by the author¹ that particles of one liquid suspended in another can be retained by suitable media, while, on the other, colloidal particles of sub- and even amicroscopic size can be separated by a variety of membranes. The procedure last mentioned is known as "ultra-filtration," and, while it is an important instrument of research, has not so far found application on an industrial scale; such application, however, should be quite feasible, a point which will be referred to again.

The first and fundamental point to be noted is that, for a given system of solid and liquid, the whole problem is completely determined physically. The size of the pores in the septum is fixed or has, at any rate, an upper limit; the largest number of pores of such size is, of course, desirable, but this is a technical matter and simply means a choice among a comparatively small range of materials. As soon as filtration begins the pores in the surface of the filtering medium are throttled more or less by the particles which settle on them, and as it proceeds the liquid has to escape through these throttled orifices and through a layer of particles of increasing thickness. The structure of this layer is also fixed by the size and shape of the particles, and is, for a given precipitate, remarkably constant. The resistance offered to the flow of liquid varies considerably from one material to another, but in all cases it increases as the thickness increases, until a limit is reached, i.e., until, with a given pressure the rate of flow becomes so small that it is advisable to discontinue the process. This limit is an *economical* one only; it depends, roughly speaking, on the way in which higher pressure increases the first cost of the plant, and, the pressure being given, on the balance between the cost of obtaining a thicker "cake" and the cost of removing it at more frequent intervals. The proper adjustment of these factors presents no difficulty to anyone experienced in designing filtering apparatus, and should be left to him.

The second point is that since the structure of the cake is fixed by the size and shape of the particles, not only the pressure required to force through a given thickness of it, but also the percentage of mother liquid remaining in it at the end of the operation is fixed within surprisingly narrow limits. It is not affected by the design of the apparatus nor by the pressure used—a point which seems self-evident, but is realised apparently by an exiguous minority of technical men. No experience is more common than to be asked to design a filter which will turn out a cake containing "not more than 20% of mother liquor," the cake being, e.g., calcium sulphate, which contains about 40%. This

figure is the same whether filtration has taken place in filter presses or on vacuum filters, through filter cloths or through porous tiles. Only actual experiment can, in the case of an unknown residue, give any information regarding the amount of liquid retained by it. It is hardly necessary to say that the appearance and consistency of the cake are no guides; an excellent "cake," say, of calcium carbonate may turn to a fairly fluid sludge during carting, owing to a slight rearrangement of the particles. In cases where the particles are not solid crystals, but themselves aggregates, the moisture content may be remarkable while the cake can still be handled perfectly. Thus a cake of the "magnesium carbonate" used as non-conducting covering retains about 75% of mother liquor, owing to the very peculiar structure of the material.² The author once showed a specimen of this cake to a client used to China clay, who guessed the percentage of moisture as 25%, or thereabouts.

The case appears even more complicated when the residue is highly hydrated, *e.g.*, anorphous silicic acid. In this case the residue contains not only the mother liquor between the particles, but the water of hydration in the latter, all, or nearly all, of which would be driven off on drying at 100° C. The only way to determine in such a case the percentage of mother liquor, as distinct from water generally, is to titrate whatever constituent of the mother liquor is most characteristic.

In a great number of processes it is necessary to remove the mother liquor as completely as possible, either because it contains the valuable constituent or because its presence in the cake is detrimental. The most common method is to displace it by water (or other solvent), *i.e.*, by "washing" the cake, as it is usually called. The ideal—displacing the mother liquor by an equal volume of water or solvent—is practically unattainable, as a certain amount of diffusion is unavoidable, but where this is slow the volume of wash-water may be very little in excess of the volume of mother liquor to be displaced. The process of washing resembles the process of filtration, with two important differences: the liquid passes through a constant, instead of a gradually increasing, thickness of residue, and the process, unlike filtration itself, is not self-regulating. To illustrate this point, we may take the case of a suspension being filtered through a material, the porosity of which varies slightly at different portions of the surface. The liquid passes more rapidly through the more porous portions, and a correspondingly larger amount of solid is deposited in a given time, which checks the flow and tends to equalise it with that through the less porous parts. If wash water is now passed through, the difference in porosity, although greatly reduced by the layer of deposit, will still cause the flow of wash water to be more rapid at some spots than at others, and this inequality no longer can correct itself, so that washing is uneven. Differences in the structure of the cake, due to other causes, will have the same effect.

The point to which washing is carried is again settled by economic considerations—such as the balance between the cost of evaporation and the value of the dissolved substance—unless, for instance, traces of the mother liquor are absolutely detrimental to the purpose for which the residue on the filter is required. If this is the case, the end point is by no means easy to determine; generally speaking, it is not sufficient to test the washings only, but the cake itself should be examined. Apart from very exceptional cases, adsorption always occurs on the particles of the cake, and although the washings show no reaction, a thin layer of adsorbed solute is nevertheless present, which may be discovered by testing the cake itself. As the latter is dried, the concentration of the adsorbed solute in-

creases and may attain quite objectionable proportions even when washing has been carried so far that the last washings show no reaction. The case is aggravated when the particles of cake are themselves porous, *e.g.*, materials produced by fusion with alkali or the like. In these cases the wash water may quite rapidly displace the mother liquor between the particles, but the liquor in the pores of the particles can escape only by diffusion, which is necessarily slow. When these conditions prevail, even the cake may appear neutral after prolonged washing, but shows marked alkaline reaction again after standing for some time, during which diffusion out of the particles into the water between them occurs. It is therefore quite useless to hasten washing, and the sound procedure is to make it so slow that it proceeds *pari passu* with diffusion. This, again, is a state of things which cannot be altered by the design of the apparatus or by increasing the working pressure, but must be accepted as following inevitably from the nature of the material treated.

Both during filtration and during washing it is necessary to maintain a difference of pressure between the two sides of the septum. How great this is to be and how it is produced are technical and economical problems. The function connecting the rate of flow through unit area of a given material with the difference of pressure is not known, and it must obviously be complicated in the technical case, *i.e.*, a layer of increasing thickness building up on a porous surface which remains constant. Even for a porous material alone, or for such a material covered by a definite layer of particles, the function is certainly not linear, or, in other words, Poiseuille's law does not hold. It has been quite frequently assumed that it does, but even *a priori* there appears to be no reason why it should, since the pores in the filtering materials used technically are quite certainly not cylindrical. In the few cases investigated by the author³ the curve plotted with rates of flow as ordinates against pressures as abscissæ shows an inflexion and then approaches a parabolic type.

As the pressure is applied to or through the liquid in which the particles are suspended, the latter are in no sense pressed together, but are simply left behind as the corresponding quantity of liquid escapes through the septum. It therefore follows that the structure of the cake and its content of mother liquor are not affected by the pressure employed—a point on which the most common and serious misconceptions exist. It need hardly be said that this statement does not apply to centrifugal filters, in which the structure of the cake also depends almost entirely on the shape of the particles, but in which acceleration is imparted to the liquid, so that—in ideal cases—the whole of it may be removed.

If a difference in pressure of about 14 lb. per sq. in. is sufficient, it may, of course, be produced by maintaining a vacuum on one side of the septum, while the liquid to be filtered is exposed to atmospheric pressure on the other. The case does not differ theoretically from any other, but the technical differences between it and filtration under pressure (in the technical meaning) are so great as to justify separate treatment. The most striking feature of the vacuum filter, as this type is called, is the accessibility of the cake during and after its formation. Apart from the facility of removal, this is of advantage in permitting defects in the uniformity of the layer, which render washing imperfect, to be corrected. On the other hand, vacuum filters cannot be used for liquors having a high vapour pressure at the time of filtration (*i.e.* volatile or hot) unless a condenser is provided.

The accessibility of the cake makes possible the design of the various types of "continuous" filters, into which, as into other purely technical details,

it is not proposed to enter here. Another very interesting possibility remains so far unexplored, *viz.*, the combined use of filtration and decantation. Many of the more common precipitates settle fairly rapidly, either because the particles, although of low specific gravity, are large—*e.g.*, calcium sulphate or calcium carbonate as arragonite (*i.e.*, precipitated from hot solutions), or because the specific gravity is high, as with barium or lead compounds—over 6 in the case of the chromates or sulphate of the latter. To take a fair numerical example, we may assume a rate of settlement of 1 cm. per minute. If this suspension is now fed at one end of a long vacuum filter at such a rate that it will take, say, 1 min. to reach the opposite end, there will be a depth of 1 cm. of clear liquid from the surface, which can be continuously drawn off over a suitable weir, provided, of course, that the rate of feed is sufficient. Calculation can only be quite approximate, as liquid escapes already through the filtering medium on the way to the weir, and as, furthermore, the velocity of settlement is affected by the horizontal flow across the filter and the vertical flow towards the filtering surface. Experiment would be quite easy, and the method seems to deserve trial in many cases, especially where the solid matter is coarse or heavy and the liquid itself runs to waste, so that a very slight turbidity would be of no consequence.

It is obvious from the foregoing that the process of filtration is quite independent of the nature of the filtering material employed, and the point would hardly deserve mention were it not that misconceptions seem to exist even on this self-evident matter. The conditions the filtering material has to fulfil are three: It must have pores of the required size and as numerous as possible; it must be of sufficient strength mechanically to stand the pressure applied, suitable methods of support being assumed; finally, it must be chemically indifferent to the liquids to be filtered. As regards the first two requirements, textile materials have very considerable advantages, and especially the slight thickness sufficient to bear considerable tensile strains makes possible the design of apparatus, such as filter presses, possessing a large filtering surface in a small space. As regards the third one, they are less satisfactory, and the use particularly of woollen filter cloths (for acid liquors) is becoming economically impossible. These cases can be dealt with by the use of porous tiles or plates either consisting of silica or materials of high silica content, or of carbon. The latter material is ideal, as it resists both acids and alkalis; it is, of course, understood that the material consists entirely of carbon and not merely of carbon particles agglomerated by a silicious binding agent. Such porous plates, made by carbonising at high temperature a mixture of ground coke and tar, have been made in Germany for a considerable time, but their manufacture has not so far been taken up in England or the United States. This material enabled the author to solve a problem which, if not important or of frequent occurrence, is certainly interesting, *viz.*, the filtration of hydrofluoric acid. A vacuum filter of antimonial lead, with carbon plates as filtering medium, was used, and it seems doubtful whether any other combination could have answered for the purpose.

A drawback of such porous plates is their thickness, which is called for more by reasons of manufacture and transport than by the conditions of use, as (apart from the difficulties of using suitable materials of construction) it is next to impossible to devise apparatus of the filter press type. The filtering surface to be obtained with a given volume and weight of apparatus is therefore necessarily smaller than in filter presses. In cases where a small amount only of solid material, which can be run to waste, has to be removed, ceramic materials offer an interesting possibility, *viz.*, the use of hollow cylinders,

i.e., "filtering candles" of large size. A large number of these can be assembled in a small space, the residue being removed by reverse flow and subsequent rinsing and flushing. The author has designed such filters for corrosive liquors having a filtering surface of about 105 sq. ft. in a volume of about 22 cub. ft., a ratio comparing favourably with that of filter presses (which would have been inapplicable). At present such porous cylinders are not manufactured in this country, but there appears to be no reason why they should not be.

A third type of filtering material remains to be mentioned, which so far has found application only in research and on the laboratory scale, but appears to be capable of much more extended use. This comprises the membranes generally described as "ultra-filters," which are capable of holding back particles of submicroscopic size. Those used in the laboratory are prepared by impregnating filter paper with collodion (*i.e.*, solutions of nitro-cellulose in ether-alcohol or in glacial acetic acid) and gelatinising the latter by immersion in water. This removes the solvent and leaves behind a gel of nitrocellulose, the permeability of which can be regulated within wide limits by choosing the concentration and controlling the removal of the solvent. There seems to be no reason why textiles should not be treated in the same way as paper, in which case the membranes could be employed in apparatus of the filter press type. They have to be protected from drying, but this is not difficult, and such filters could probably take the place of pulp and similar filters where very brilliant filtrates are required.

THE FILTRATION OF COLLOIDS.

BY W. R. ORMANDY, D.SC.

The ordinary methods employed for the separation of solids from the liquids in which they are suspended are:—1. Subsidence and decantation. 2. Ordinary filtration. 3. The use of centrifugals. 4. The use of the filter press. Whatever method is employed, efforts are always being made in the direction of producing a precipitate which is as dense and as crystalline as possible. Unfortunately some precipitates cannot be converted by any ordinary treatment into a form which render them amenable to easy treatment by any of the methods referred to above. Precipitates such as hydrated oxide of iron and similar substances of a slimy character are often very difficultly amenable to any treatment. The precipitates may be formed in hot solutions, they may be allowed to stand, or boiled; but in many cases such treatment does not lead to a suspension which can be readily handled.

The special method of treatment with which we have to deal now depends on the utilisation of certain properties of finely divided particles in suspension. This new process for the application of physico-chemical laws is in many respects so new that it is necessary to deal shortly with the underlying principles before the methods of their application, and the limitations of the process can be properly understood.

Colloids can be divided into two groups, the reversible and the irreversible. To the reversible group belong such substances as glue, gelatin, which can be dissolved in water, dried, and again dissolved in water without any great alteration in properties. To the irreversible group belong such substances as albumin, which after treatment with boiling water become absolutely insoluble. For the most part, however, the nature of the colloid is largely dependent upon the size of the particles.

Sufficiently fine particles when suspended in water exhibit what is known as the Brownian movement, which is more energetic the smaller the particle. This Brownian movement is now regarded as the visible symbol of molecular bombardment, as has been largely proved by the beautiful researches of Professor Perrin. Generally speaking particles of matter exceeding 0.0001 mm. in diameter will eventually settle from solution. It happens that this is about the limit of microscopic visibility. The fact that particles below this limiting size do not settle means that the molecular and electrical forces outweigh the action of gravitation. So far back as 1869 Jevons noticed that the intensity of the Brownian movement of clay particles was increased by the addition of traces of certain types of substances and inhibited by the addition of other types of substances. In 1895 Bliss noticed that a clay suspension exhibited increased Brownian movement with the addition of traces of alkali, but that the addition of further quantities again reduced the movement.

It has long been known that the addition of certain types of chemicals tended to cause coagulation of colloids suspended in water; thus the addition of calcium hydrate and aluminium sulphate to bring about the settlement of sewage sludge is ancient history. Weber many years ago showed that the addition of considerable quantities of sodium carbonate and sodium silicate to mixtures employed in the making of pottery ware caused such mixtures to be thinner. This principle was utilised by him to enable "slips" to be prepared containing much more clay substance, flint, Cornish stone, ball clay, and other ingredients employed in pottery making to the gallon, and such "slips" are employed in the casting of pottery-ware in plaster moulds.

These are all illustrations to show to some extent the position of knowledge relating to the effect of electrolytes on colloidal suspensions. It remained for Count Schwerin to see the bearing of these little-studied laws in their commercial application. A very brief history of his work will be useful in showing you how a few accidental observations scientifically followed up have led to developments of the greatest technical importance. Count Schwerin at the University was working on the problem of removing the musty products of decomposition from albuminous materials, and in the course of some electrical experiments noticed that his colloidal products collected on the poles which he was employing in his experiments.

Being greatly interested in the problem of drying peat he tried similar experiments on a peat suspension, and found that the peat actually did travel to the anode and was deposited thereon. His efforts at that time were directed rather to the utilisation of electro-endosmosis to the de-watering of peat, and to justify this end the peat magma was pressed between perforated plates which were respectively anode and cathode. On cutting through the dried peat mass so obtained he noticed that, although the peat suspension originally employed had been thoroughly mixed, nevertheless the section of the dried peat showed layers parallel to the anode, and he gathered from this experiment that under the influence of the current the various bodies in the suspension travelled with different velocities. Finding that one of the layers consisted largely of clay substance, the experiments were tried with a clay suspension, and it was found possible to deposit clay out of a water suspension on the anode. Starting from this basis the "Osmose machine" was gradually developed (this machine will be described later), but it was found that while one clay would deposit, another apparently similar clay did not react. Much experimental work led to the discovery that

certain clays shaken with water have particles which apparently carry no charge. The next development was to make use of the fact that most colloids can and do adsorb considerable quantities of electrolytes to which they may be exposed, and it was found that by the addition of very small traces of suitable electrolytes such as caustic soda, and the like, the previously inert clays were rendered amenable to electrical action. Even now the difficulties were not overcome, for it was found that a few clays were still impossible of treatment. In many cases this proved to be due to the presence of traces of divalent salts which were soluble in water, and, as has already been pointed out, these divalent and trivalent compounds have an extreme power of neutralising the so-called peptising action of the univalent alkalis, bringing about the coagulation of the clay subsidence. Such cases can only be met by previous chemical treatment directed to the conversion of the coagulating electrolytes into insoluble salts.

It is by the utilisation of selective adsorption and by choosing diaphragms of suitable polarity that it has been possible to separate from blood serum the fibrinogen, the euglobulin, and other substances, leaving a pure paraglobulin behind. The practical application of this discovery becomes obvious when we learn that in the preparation of anti-diphtheritic serum from horse serum it is possible to separate an anti-diphtheritic product having ten times the strength of that usually prepared directly from the serum. This achievement is based not only on the application of the principles above referred to, but on the discovery that the anti-toxin in blood serum is practically entirely combined with the paraglobulin, and that by isolating the paraglobulin from the anti-diphtheritic horse serum the concentration for medical purposes is increased manyfold. Obviously the removal of large groups of little-known and complex nitrogenous substances from the serum leaves a product which is not only medically more active, but carries with it a greatly diminished quantity of not only inert, but possibly harmful products. So much then for the general laws upon which the Osmose process is based.

In what follows reference will be made to the behaviour of a clay suspension, because clay is in many respects a typical colloid suspensoid, and the methods of dealing with clay have been further developed than any others. It is found that if one part of plastic clay be mixed with one part of water, a creamy mass is produced. In the case of a very plastic clay, i.e., generally one having very finely divided particles, the mixture will be almost as thick as butter, whereas with a meagre clay not very plastic, such as ordinary china clay, the mixture may be only a thin cream. If to these mixtures we add a small amount of alkaline electrolyte, say 0.03% on the weight of the clay, a wonderful alteration is brought about in the physical properties of the mixture. In both cases the buttery or creamy mass will become very thin and fluid. The suspended colloid has been converted from the gel condition into the sol condition, and now all the particles are electrically charged, and to a very large extent have become dispersed and are in a much more finely divided state than was previously the case. Such a dispersed suspension is exceedingly difficult to filter by ordinary means, but use can be made of the fact that the clay particles are charged and can be deposited on an electrode of suitable polarity.

The anode of the machine used is a rotating drum made of an alloy to resist the corrosive action, whereas the cathode consists of copper strips placed round the anode, and distanced about $\frac{1}{4}$ in. therefrom. The bottom of the containing vessel contains paddles to keep the clay in suspension. The clay suspension consists of clay particles having

a comparatively strong negative charge and other substances having a very feeble negative or no charge at all.

In the electric field between the cathode and the anode the clay particles are strongly attracted to the anode. The moment a film of clay has been formed on the anode the water contained therein is violently ejected towards the cathode, and this stream of water tends to sweep away all but the particles having a high negative charge, which, in spite of the water current, are drawn to the anode. The lantern slides show a sample of raw clay, then the impurities which settle out of the clay after the addition of the electrolytes, then the impurities which are rejected by the Osmose machine, and finally the clay as taken up on the anode.

Although such a process cannot be considered as an ordinary filtration process, nevertheless it is, *inter alia*, a process for the continuous separation of suspended matter from suspending liquid with simultaneous partial drying of the solid product. Obviously such a continuous process can only be employed where large quantities of material have to be handled, but the same principle can be embodied in the Osmose filter press, which consists of an ordinary type of press made of insulating material, the filter cloths being placed upon insulated pieces of conducting material, such as wire gauze or the like. Into such a chamber the clay suspension can be passed under just sufficient pressure to ensure that the chamber keeps filled. Without the application of electricity under these conditions there will be no filtration, for the filter cloths would be choked from the first moment. By the application of a potential of 60 volts, however, the water is forced out through the cathode, and a firm, hard cake results very rapidly, and even in the case of plastic ball clay a 3-in. block can be made in an hour containing less than 30% of water. It will be impossible to produce a 3-in. block of ball clay in an ordinary filter press with 200 lb. per sq. in. in days, let alone hours.

The essential difference between the Osmose machine and the Osmose filter press lies not only in the continuous action of the Osmose machine, but in the fact that the machine brings about a certain selective purification or separation, whereas the filter press by its nature merely serves to collect the whole of the suspended product.

THE "STURGEON" SELF-DISCHARGING CENTRIFUGES FOR SEPARATING SOLIDS FROM LIQUIDS.

BY R. A. STURGEON.

Careful consideration of the various attempts which have been made to construct a self-discharging centrifuge led to the following basis for design being laid down:—

(1) The surface liquor and the lightest portion of the solids must be removed before the main deposit is discharged.

(2) There must be no attempt to overcome, by direct means, the centrifugal force of the deposit. The only forces to be overcome must be frictional resistances, while all the main forces must be balanced in some way.

(3) The power for effecting the discharge must be obtained through the main drive to the centrifuge, and must not be dependent upon accessory machinery.

(4) The effective volume of the separating chamber must be the maximum obtainable for a given diameter of machine.

Several attempts were made to design a machine to meet these conditions, but the results were not very satisfactory until the use of the pressure produced in a liquid by centrifugal force was introduced to operate the discharging mechanism.

"Sturgeon" Centrifuge for Combined De-watering of Solids and Clarification of Liquors.

The type of separator designed along these lines for combined de-watering of solids and clarification of liquors is shown in the accompanying figure,

which consists of two half-sections—one through the valves in the top cover, and the other through the levers which hold the bottom cover up to its seating. The cylinder, A, has a fixed cover, B, at the top, and a movable cover, C, at the bottom. The movable cover is held on its seat by weights under centrifugal force acting through the bell-crank levers, D, which allow of a limited lift. The piston, E, which slides up and down the shaft, F, has a large hollow boss, G, through which the liquid under treatment may pass from the apertures in the hollow shaft. To the bottom portion of the boss is attached a disc or plate, H, which forms a joint with the inner edge of the movable bottom cover. Attached to the bottom cover are valve rods, K. When the piston reaches its bottom position it lifts the movable cover off its seat, thereby causing the valve rods to open the valves, L. The shaft is rotated by means of the pulley, M, and, of course, the cylinder and all parts connected thereto revolve with it.

The machine is started and the liquid to be treated enters the machine through the hollow shaft, F. It passes through the apertures into the hollow boss of the piston and thence into the cylinder. The solids are deposited on the walls of the cylinder as the liquid passes through, and the clarified liquid is discharged over the concentric weir, N, and into the chamber, O, whence it is carried away through the pipes, P. When it is time to discharge the deposited solids the supply of liquid is cut off, and water is admitted to the top side of the piston through the pipe, Y.

As soon as the piston commences to descend the joint near Q is broken, and the surplus liquid flows away into the trough, R, and is carried away by the pipe, S. As the piston descends the liquid continually overflows the weir, Q, until only solids are left. These are further squeezed, and much of their accompanying liquid is removed, flowing over the weir, Q. This liquid is necessarily very dirty, and is kept separate from the main effluent, which would otherwise be contaminated. Finally, the pressure under the piston becomes so great as to overcome the pull of the levers, D, and to lift the

cover, c. The solids are discharged on the revolving circular plate, v, whence they are scraped off by the knife, w, and fall down the chute, w. As the cover, c, lifts the valves, t, open, and the water above the piston is discharged into the trough, x. This discharge may be made tangentially in the opposite direction to that of rotation, so that the pressure which has been imparted to the water by the machine may to a great extent be restored during the discharge. Thus the horse power required to effect the discharge of the solids is reduced to a minimum.

As soon as the pressure of the liquid falls sufficiently, the cover, c, closes, and when all the water has been discharged the machine is ready for a fresh charge of the liquid under treatment. This forces the piston up to its top position, closing the valves, t, and coming to rest on the seating, the upward pressure being sufficient to maintain the joint. The machine then fills up, and the operation proceeds as before.

In this type of machine the effluent is discharged at the maximum distance from the deposit, and the main effluent, the liquor squeezed out of the solids during discharge, the solids, and the water used for discharging are all passed into separate compartments.

A simpler type of machine was also described to deal with cases in which clarification of liquor is the essential factor, the amount of moisture in the solids being of small importance; also another type of centrifuge for clarification and grease recovery.

THE SHARPLES "SUPER-CENTRIFUGE."

BY S. H. MENZIES.

The Sharples "super-centrifuge" applies the settling action of gravity highly intensified in two classes of operation, viz., that in which solids are settled out of liquids, which may be termed "clarification," and that in which one liquid heavier or of higher specific gravity is settled apart from another liquid of lower specific gravity. For the purpose of the paper this latter operation will be termed "separation."

With the Sharples "super-centrifuge," the action which takes place in the case of "clarification" of a liquid from suspended solids is a "subsidence" pure and simple and not in any sense a "filtration."

Since centrifugal force varies directly with increase of diameter, and as the square of the speed of revolution, the centrifuge in question has been constructed of tubular pattern.

The rotating member, or "bowl," is both supported and driven from the top, being otherwise entirely free to find its own axis. By these means the machine is operated with the minimum of wear and tear. One main ball-bearing constitutes the sole point in the machine at which friction has to be taken into account. The drive, arranged immediately above this main bearing, takes four alternative forms, viz.:—

- (1) A pure belt drive from line shaft.
- (2) Direct steam drive by means of a turbine wheel fixed to the tube or bowl spindle.
- (3) Indirect electric drive, i.e., individual motor mounted on the centrifuge body and driven by short belt and idler pulley on to the head of the bowl spindle.
- (4) Direct electric drive in which the motor armature is mounted on and an integral part of the bowl spindle. Mechanical friction losses are thus limited solely to those of the one ball-bearing

which carries the rotating bowl. A considerable reduction in consumption of power is effected in this instance.

At the bottom of the bowl a short extension runs with a definite permitted clearance in a bushed socket, serving as a guide during the running up to speed of the bowl, when slight vibration or oscillation may occur. The liquid to be treated is admitted through the hollow centre of this extension of the bowl either under greater or less head, or in certain cases positive pressure, according as viscosity or other considerations demand. Settlement takes place during the upward travel of the liquid, which discharges at the top of the machine through one or two outlets, according as the process in hand is that of "clarification" or "separation." In the former case the suspended solids normally are deposited on the inside wall of the tube or bowl, and these solids are intermittently removed from the bowl as and when it becomes fully charged.

In certain industries a large diameter and slow-running centrifuge may be an economic primary stage to the final intensive treatment in the "super-centrifuge." By this means complete clarity would be secured in liquors heavily charged with solids which could not otherwise be economically handled in the "super-centrifuge." As an alternative to this liquors high in suspended solid content are given a preliminary gravity sedimentation before centrifuging.

Two typical processes in connexion with "clarification" which might be cited are those of dry cleaners' benzine recovery and the clarifying of lacquer or nitrated cellulose. In the former we have an instance of a heavy suspended material in an extremely light liquid, whilst in the latter very light solid material is suspended in a heavy and highly viscous liquid.

The process of centrifugal clarification with continuous discharge of solids.

In both cases in the "super-centrifuge" clarification is complete and the suspended solids entirely eliminated. These two cases, however, afford good

examples of the manner in which physical characteristics affect capacity of the machine. In the case of benzine clarification the flow through a Sharples "super-centrifuge" can be taken comfortably to 250 galls. per hr., whilst in the case of the nitrated cellulose, where the process is one of eliminating fine vegetable fibres of cotton or pieces of cotton-husk, the flow through a Sharples machine to secure the best grade of lacquer entirely free of all solid suspension usually does not exceed 70 to 80 galls. per hr.

In one factory the introduction of a Sharples "super-centrifuge" completely revolutionised the process of manufacturing this nitrated cellulose. Prior to its installation the firm in question found it essential, in order to maintain the high character of their output, to purchase only the most expensive grade of cotton wool, whilst after the introduction of the clarifying process by means of the "super-centrifuge" it was unnecessary to pay any particular regard to the grade of cotton which was employed, since any impurities remaining after nitration were easily and completely removed, and the final product still maintained at its high excellence. A reduction in the contributory cost of this raw material by over 50% was thus effected.

In the "super-centrifuge" treatment of varnish one of two objects may be accomplished. Where ageing is not carried out to any great extent the complete removal of all suspension which would mar the coat or settle in the can is effected, and a brilliant product results. In the case of varnish which has to be aged, treatment by the intensive "super-centrifugal" force will secure a firm, thin layer of sediment not easily disturbed on decantation, as against the bulky sludge, which proves troublesome by reason of its ready disturbance during decantation.

Where "separation," as defined earlier in the paper, is alone in question two characteristics are essential in the constituent liquors, viz., immiscibility and difference of specific gravity.

The Sharples super centrifuge, laboratory type, turbine driven.

Specific gravity, viscosity and the globule character (in the case of fine emulsions), besides

other factors, all enter into the consideration of the type and design of bowl.

In a number of cases contributory processes to the central function of the "super-centrifuge" have been worked out by careful test and research, a prominent example being the separation and continuous discharge of amorphous wax from cylinder stock. This result, previously impossible in a centrifuge, has been achieved by carrying out the entire process at a very low temperature and employing a carrier liquid immiscible with the oil and of greater specific gravity than the heavy wax, upon which the wax is floated off in a continuous discharge. The diagram of action in the super-centrifuge shows very clearly what happens in the bowl.

The laboratory machine (see fig.) is a still further development of the sacrifice of diameter to revolutions, and emphasises the resultant gain mentioned at the outset, since in the commercial or full-sized Sharples super-centrifuge a separating force is developed at 17,000 r.p.m. of 16,950 times that of gravity, whilst in the laboratory machine a force over 40,000 times that of gravity is developed, and a means for effecting hitherto impossible separations, as also for facilitating qualitative and quantitative physical analyses, is afforded.

The opportunities presented by the machine include such processes as the separation of finely-divided wax from an alcoholic solution of shellac; the separation of bacteria from serums, for which the machine found a wide use during the recent war; separation of pigment from paint and enamel, and quantitative analysis of these.

Many complete processes have been worked out in which the super-centrifuge itself constitutes but one feature; amongst these may be mentioned the recovery of neutral wool fat from scouring effluent; the separation of vegetable oils from soap stock; the dehydration of water-gas tar; clarification of glue and of nitrocellulose liquors, and the separation of wax from mineral oil as before mentioned.

As an illustration of the action of the super-centrifugal force upon serum, a sample submitted for treatment from which all the corpuscles had been previously filtered off, and which appeared absolutely free of suspended matter clogged a Berkefeld filter after passing 200 c.c. Treatment through the super-centrifuge eliminated the bacteria thus evidenced to the extent that 20 litres did not clog the same Berkefeld filter.

DESIGN OF MECHANICAL FILTERS.

BY BALFOUR BRAMWELL.

The principal difference in filtration with the mechanical filter and the slow sand-bed is in the speed of filtering. In the mechanical filter this speed is approximately 40 times that of the slow sand bed, consequently the mechanical filters are often termed rapid filters to distinguish them from slow sand beds.

In the slow sand bed the straining action is confined almost entirely to a thin top layer of the filtering material, whereas in the rapid filter the whole depth of bed is made use of before the filter is thrown out of action for the cleaning process.

Slow sand beds generally work for months without scraping, but the rapid mechanical filters are usually designed so that the cleansing process is carried out in the case of waterworks once per 24 hours, or sometimes once every 12 hours, and in the case of filters for industrial purposes once per working day, or in some cases once every 6 hours.

The usual speed of filtration for slow sand beds is approximately $2\frac{1}{2}$ galls. per sq. ft. of superficial area, whereas the most economical and satisfactory speed for design of mechanical rapid filters is 100 galls. per sq. ft. when dealing with the

purification of ordinary average waters met with. With a better class of water this speed can be increased 20%, and it is not uncommon, but cannot be recommended, to have filters that are being cleansed every 6 hours working at a speed of 140 galls. per sq. ft. When the water to be purified is very good, and requires very little chemical treatment, the speed of filtration can be increased two or three times, but it is rare that such waters are met with except under exceptional circumstances.

Slow sand beds are much more sensitive to choking than rapid filters, since the straining action in the former is confined to a very thin layer of filtering material. With rapid filters agitation of the surface of the filter bed is often advantageous. In order to obtain the best results from rapid filters chemical and coagulant treatment must be used. Provided sufficient time is given for storage and for the chemical action, precipitation, and sedimentation to take place, there is no need for filtration.

In our days, however, it is a mistake to build huge reservoirs for the purpose of storing water to obtain purification when this purification can be achieved by quite a short storage and rapid filtration, for instead of months of time for the process only hours are required with subsequent rapid filtration. It is entirely wrong, however, to depend too much for purification on chemical treatment. Want of filtration or inefficient filtration often means overdosing with a germicide to obtain the necessary result.

The cleansing of the filter bed is a very important operation. At every periodic cleansing of a mechanical filter the whole bed should be disturbed and uniformly agitated and cleansed from top to bottom. In all mechanical filters, with one exception, this is effected by a voluminous reverse flow of water, which lifts and eases the bed before the agitating devices operate. The exception is the filter working on the "turn-over" principle, in which the whole chamber is made to revolve slowly.

In all the other filters the reverse flow has to be concentrated by means of restricted orifices, and without such reverse flow under a considerable pressure cleansing cannot be efficiently effected. In the case of air or steam injectors it has been found that a reverse flow of air or steam through the bed is useless without a voluminous supply of water.

In the "turn-over" filter, by revolving the whole of the filter chamber to upset the whole filtering material only a comparatively slight reverse flow of water is necessary to wash the impurities to the surface of the bed. The following are features affecting the efficiency of cleansing, for it cannot be disputed that the method adopted for the cleansing is really the crucial feature in the mechanical filter. With the "turn-over" principle there are no nozzles in the bottom of the filter. The bed rests merely on a double thickness of perforated plates with holes superposing, having sandwiched in between them a fine mesh of strong copper or bronze gauze. The area, therefore, through the bottom is nearly equal to the area through the perforated plates, and is very large. The gauze is well supported, and only exposed in the perforations, which are half an inch diameter. There is, therefore, no restriction to the passage of water, and practically no loss of head from this cause.

In rapid filters using chemical coagulant treatment the minimum depth of bed of one grade should not be less in the smallest sizes than 2 ft., and in large waterworks filters it should be from 2 ft. 6 in. to 3 ft.

The best filtering material is undoubtedly crushed quartz, because it is hard and sharp and less liable to trituration, and is practically non-absorbent. Natural sand gives the same filtering

efficiency, but it does not clean quite so well owing to its rounded particles, neither does it pack so well. It is absorbent, and most of it is composed of a soft, triturable material. Quartz is, however, very expensive and difficult to procure at the present time.

All material, whether mechanically crushed or natural, should be free from dust or very fine particles, and should, therefore, be riddled. The grade of filtering material should, of course, be made as uniform as it is possible to obtain, but in practice absolute uniformity cannot be expected; therefore, a system of cleansing which necessitates a reverse flow of water at such a high head and of so great a volume that it throws the finer particles of the filtering material to the surface is distinctly at a disadvantage.

The design of the "turn-over" filter was the outcome of trouble experienced in imperfect cleansing of the bed in Reeves' filters when dealing with a very bad water to be used for industrial purposes, especially water containing colloid matter, of which most rivers contain a certain proportion, and which is most difficult to deal with. Unless the bed is disturbed in every portion at each periodic cleansing the tendency is for the portions imperfectly cleansed to become gummed up in such a manner that the means provided for agitation, in order to loosen and wash out the impurities, are insufficient. Rakes could not reach all the parts of the filter bed. The result of this experience was that the "turn-over" principle was thought of, and the very first filter installed is still successfully at work to-day.

The sides of the chamber in the "turn-over" filter are curved or spherical, and have the same beneficial packing effect that cone sides have. The life of the copper gauze on which the filtering material rests averages five or six years. It costs only a few pounds to replace, and the work of replacing can be executed very quickly by turning the filter on its side, fixing one half in at a time without removing the filtering material. The bottom and gauze can also be washed with a hose at any time and inspected without removing the filtering material.

There is practically no loss of filtering material in the cleansing of the "turn-over" filter, because, unlike other filters in which the wash-water is being discharged at the same time as it is being allowed to flow into the filter chamber, the filter is specially arranged so that it is impossible to inject and eject the wash-water from the chamber at the same time. By this arrangement it is possible to place the discharge opening for the dirty wash-water close down to the surface of the bed, and, therefore, get rid of the dirt more thoroughly and rapidly by siphoning action.

Mr. E. A. ALLIOTT read a long paper on "Plate and Plate Frame Filter Presses," which will be printed in a subsequent issue of the Journal. An abstract of Mr. W. J. Gee's paper, "A New Process of Centrifugal Filtration," will also appear later.

ANNUAL DINNER.

The annual dinner of the Society was held in the King's Hall, Armstrong College, Newcastle, on Wednesday evening. Professor Henry Louis presiding.

After the usual loyal toast had been honoured, Mr. FRANCIS PRIESTMAN, Chairman of the Ashington Coal Company, Ltd., proposed "The Society of Chemical Industry." As a commercial man he was glad to say that he recognised what a great deal

depended upon such a Society as theirs. The coal trade was indebted to the chemist for a great deal in the way of fuel saving. He recalled how at his by-product works the German chemists had been replaced by British at the earliest possible moment, and the results had been equal to, and often better, than those obtained when Germans had been employed. The Society had since its inception done most valuable work both in disseminating knowledge and in bringing together a large number of scientific people; such gatherings were bound to be of benefit to the nation. He concluded by hoping that the good work of the Society would continue, and that the membership would increase and the Society generally become very prosperous. He coupled the names of the President and Prof. Louis with the toast.

PROF. LOUIS, replying to the toast, thanked Mr. Priestman on behalf of the Society, the President, and himself. Most of them were aware of the reason why he was presiding that evening. It was directly due to the effects of war stress on their President. Owing to his strenuous exertions on behalf of the nation Mr. John Gray was not able to be with them that night. His name was not widely known. He was one of those who had worked quietly, steadily, and unostentatiously, but without him and men like him the country would have been at a sorry pass to-day. Mr. Priestman had indicated that at last the British chemist had come into his own. If there were such a thing as a bright spot in the war it was that their industry and chemists had at last received national recognition. The academic chemist had been brought to apply his knowledge to factory work, with what great results they knew. They had succeeded in bridging over the gulf between abysmal ignorance on the one side and esoteric erudition on the other. Still, scientists and teachers of science did not appear to have got that recognition from the leaders of the nation that they were entitled to; they had received less than any other class from the State. He could wish that the Government was more fully alive to the importance of sustaining the scientific life of the community. It was obvious that so long as the purse strings of the nation were held by the politicians there would be little improvement. The politician and the scientist could never have very much in common. Their points of view were entirely different. After all, the principal task of the scientist was the search for truth. He did not think anyone would accuse politicians of wasting too much time in that quest, and it was natural to suppose that politicians did not see much use in the men who followed the practice of not only looking for facts but even publishing them! Their Society was in a flourishing condition, and its membership was increasing steadily; with its 5700 members it was one of the leading technical societies in the country. Obviously, the success of the Society was bound up in the success of the chemical industry. When he had addressed them a year ago, in the first flush of victory, he had looked forward to a time of peace which would enable them to repair the ravages of war. He was afraid those hopes had been disappointed. They were still looking for a true peace which would enable them to put aside all thought of discord and get on with their various tasks. During the war, in one respect, the task had been simple—they had had one common object in view, and the nation as a whole had worked together. It seemed that the common bond had now loosened, and men were pulling in different directions. Instead of patriotism they saw the discord of selfishness. Such a state of affairs was bound to react unfavourably on all industries. The time of false prosperity would cease, and the chemical industry was bound to feel the effects of the position more than any other. The chemical industry was a key industry in only a limited sense.

It certainly held the key that unlocked the door to failure, but it was by no means certain that it held the key that opened the door to success. The road to prosperity in this country lay through the heavy key industries—coal and iron—but the road to disaster might come through the neglect of the chemical industry. Dark as the immediate future might be, and he believed there were dark days before them, he did not despair of the future. He had always a belief in the sound common-sense of the average British citizen. When they did get back to habits of steady work he believed they would find that the chemical industry had played its full part with the other industries in re-establishing prosperity, and the prosperity of the chemical industry meant also that of their own Society.

DR. E. F. ARMSTRONG proposed the toast "Armstrong College," coupling with it the name of Sir Theodore Morison, K.C.M.G., K.C.S.I., D.C.L. Armstrong College was the centre of learning in that great city, the centre of thought; a centre whose influence was perhaps unseen, but it certainly pervaded the whole county of Northumberland. Referring to the growing recognition of the chemist, he said it behoved them to rebel against the label of "stinks" which had clung to the science for so long. He put forward a plea for associating the science with colour. In the attempt to create a great dye industry he thought the association of the industry with colour was very appropriate. In proposing the toast of that College he would like them to remember the great men it would assuredly turn out—men who would take up their work quietly and without seeking public advertisement. He would like them to cultivate the virtues of efficiency and tolerance and to adopt as their watchword the lines—

"To set the cause above renown;
To love the game beyond the prize."

SIR THEODORE MORISON, replying to the toast, said that Armstrong College had been connected with the Society of Chemical Industry for many years. It was the third time they had visited Newcastle, and he was glad to see that each time they came they had been associated with the College. The local section of the Society had also worked in intimate association with the College, to the great benefit of the College. The visit of such a Society to the College made them realise the enormous opportunities of work which were opening out to modern provincial universities; it was those visits of practical men engaged in practical work which took away from the provincial college that reproach of esoteric learning. He felt that it was by the connexion of the learning of the universities with the practical work of the world that the distinctive characteristics of the new universities would be founded. He thought they would always have a special advantage that the older universities could not have, and that was in living in close association with practical men engaged in industry. The occasions and opportunities for work were not only national, but international. He advocated the interchange of students between French and English colleges, believing that a real *Entente* was only possible by individuals of both countries getting to know each other better. That interchange of pupils was a very definite work for the universities.

COL. W. C. BLACKETT proposed the toast, "The City of Newcastle," in a humorous speech. As a Durham man he was glad to pay homage to Newcastle as a centre of learning. What training he had got for his profession as a mining engineer had largely been obtained from the professors and the technical societies of Newcastle.

THE LORD MAYOR OF NEWCASTLE (Councillor Walter Lee, J.P.), in reply to the toast, said that to welcome such a Society as theirs had given him exceptional pleasure. He realised, though not a chemist, how important the chemical industry was to such an area as the counties of Northumberland and Durham. He had learned something of the great achievements of the industrial chemist in the realms of by-product coking, and he was beginning to realise how greatly his district had benefited from the efforts of scientific men.

SIR WM. J. POPE (President-elect), proposing the toast of "Kindred Societies," coupled with the Société de Chimie Industrielle and M. Paul Kestner, said that the toast introduced a large subject because the Society of Chemical Industry claimed kinship with all associations which had for their object the advancement of science and technology. He would therefore confine his remarks to the youngest of the sister-societies. The French Society of Chemical Industry was not yet two years old, but, during that brief period, it had given evidence of remarkable vivacity, and had already taken a high position among the scientific societies of the world. The French Society had, of course, to some extent modelled its procedure upon that of our own; but, at the same time, it had introduced certain novelties of method which were worthy of their most serious consideration. The monthly Journal of the French Society of Chemical Industry was a literary production, and its contents exhibited all that precision and all that genius for expression so characteristic of our neighbours across the Channel; each number contained at least one article which dealt comprehensively with some great chemical question of industrial or economic importance. In spite of the recognised value of our English journal we could not but admit that we had much to learn in the art of presentation of important matter from the official organ of our French colleagues. One other point was perhaps of importance. During numerous recent visits to France he had occasion to observe that the Journal of the French Society of Chemical Industry was on sale at the railway bookstalls; that, together with the very large amount of lucrative advertisement matter contained in the French journal, should attract the earnest attention of those who devoted themselves, so much to our advantage, to the finance of our Society. No mention of the French Society of Chemical Industry could be dissociated from the name of the man who had founded that Society, whose initiative and genius had directed its early policy, whose organising ability had enabled him to gather together a band of collaborators who had made the new French Journal one of the ornaments of modern scientific literature, and who had been, in fact, the only possible first President of the young Society. Monsieur Paul Kestner was known to all as one of those great chemical technologists who had arisen from time to time, each of whom had, in his own unique fashion, assisted in establishing the chemical industry in its present commanding position; his inventions, and the driving force with which he had vitalised those inventions and made them powerful agents in the amelioration of many of the conditions of life, had made the name of the first President of the French Society of Chemical Industry a household word in the scientific community of every civilised country. He might speak at length on this theme, but actions spoke louder than words, and our Society, in conferring its medal on M. Kestner, had proclaimed more forcibly than he could ever hope to do the position which this great Frenchman had gained for himself as a pioneer in one of the most rapidly expanding branches of productive activity. In drinking to the success of the French Society of Chemical Industry and to the health of its first President, he should carry every-

one present with him in expressing an honest desire for the establishment of a closer relationship between their two societies; each of our nations had much to gain from a more intimate alliance of this kind. The casual observer might possibly at first sight think it remarkable that so much existed in common between the most exclusive of the Anglo-Saxon races, ourselves, and the French nation, which represented the most exquisite and the most artistically-minded product of the old Latin civilisation. He was sure, however, that if M. Kestner did him the honour of replying to these few words, they would carry away the conviction that his ideals in life were identical with our own. The events of the last six years had proved to demonstration that France and Great Britain were one and indivisible in their conception of the aims, the destinies, and the honour of the human race. He desired to propose the toast of "Kindred Societies," coupling the toast with the name of M. Paul Kestner, President of the French Society of Chemical Industry.

M. KESTNER replied as follows:—"I have the pleasant task to reply in the name of Kindred Societies. It is the youngest of these Societies I am representing here; it is also, I feel sure, the one which is nearest to your hearts. Established during the war, when the French and English were brothers-in-arms on the battlefield, it has been created in a pure spirit of brotherhood. But the sentiments which link us to your Society are at the same time filial. We always consider our Society as a daughter of yours. We wish it to be a daughter of which you will always be proud, and this will be our powerful stimulus for the future. This meeting comes on the morrow of the day when the International Union of Associations of Pure and Applied Chemistry has been definitely consecrated, in a grandiose frame in magnificent receptions, in Rome. The new Federation replaces the Union which existed before the war, and in which the different nations were represented only by their associations of pure chemistry. The fact that officially there is henceforward but one chemistry, that all associations of pure and applied chemistry are united in indissoluble links represents an event of incalculable importance. Certainly there has never been any need to plead the necessity of such fusion among us. Has not the Society of Chemical Industry in the past impartially chosen its presidents within the scientific glories and within the glories of the great English chemical industry? Is not its present President, Sir William Pope, illustrious scientist, succeeding a great technologist, John Gray? If there have been water-tight compartments between the associations of pure chemistry and of applied chemistry there has never been any partition between the two chemistries, as there exists only one. If there have been some misunderstandings sometimes our associations of applied chemistry have immediately set to work to dissipate them. We look upon our scientists as our chiefs, our masters; we venerate them, and our duty will always be to honour and help them under any circumstances. Gentlemen, during the journey I have just made in Italy in company with Sir William Pope, in witnessing this complete harmony between our Societies, this full and hearty agreement between the chemists of the nations represented, I could not fail to observe from the newspapers that there is in Italy an uneasiness—that public opinion expresses reproaches against the Allies. What is the cause of this uneasiness? In the great common enterprise of *entente* and of increasing intimacy between the Allied nations it seems that there are two distinct planes of thought which run parallel. The first plane is that of the diplomats, on whom devolves the burden to take decisions, the consequences of which are incalculable. The second plane is that of associations of scientists, thinkers,

economists, and manufacturers, who are so much interested in instituting firm relations between country and country. Since the Armistice the great international problems have been dealt with by the diplomats, nearly always without any knowledge of the public, although each one of us assumes a part of the responsibility of their decisions, and each of us has to bear the consequences. Yet the people of these nations as a whole and individually know nothing about these conflicts of interest, nothing of the solutions which are proposed or adopted, and those here are ignorant of the consequences these solutions may bring on the friendly relations of people to people and individual to individual. Less than ten years ago a French writer wrote about England, for the use of his fellow-countrymen, a book entitled "l'Île Inconnue." For many Frenchmen England is an unknown island, at least unknown in regard to that which is essential in the political, economical, social, and religious life of England. Without doubt the English have come to know France a little better since the war. But even to the English recently fighting in France there remains much to learn about our country, our ways, and our common aspirations. It is Societies such as ours, our Unions of Societies, that must establish from people to people throughout the civilized world collective and individual relationships which, if they are not able to prevent the mistakes that the diplomats sometimes commit, at least correct them and partially neutralise their consequences, through the fact that they establish permanent links of brotherhood. The Union of Associations of pure and applied chemistry in a single body has created to this end a remarkable and efficacious instrument. Let us hope that it will serve as a model to other Unions, which will be formed in other domains. The scientists, the thinkers, the economists and the manufacturers will in such Unions be united, and the result will be a deeper knowledge of each nation's qualities, and therefore a reciprocal esteem, which will dissipate misunderstanding. Sir William Pope, your interest in the Société de Chimie Industrielle, and the friendship with which you have honoured me, have transformed the present toast into one of the Société de Chimie Industrielle and of its President. In the name of that society, and on my own behalf, I thank you most cordially, and join with you in the earnest desire for the more and more intimate union of associations of chemistry, and particularly for the complete and indissoluble union of the French and English societies.

VISITS TO WORKS, EXCURSIONS, ETC.

On Wednesday afternoon and Thursday parties of members visited the works of the following:—Tharsis Copper and Sulphur Co., Palmers' Iron and Shipbuilding Co., Swan, Hunter and Wigham Richardson, Ashington Colliery, John Bowes and Partners, Newcastle Alloy Co., Newcastle Breweries, and Cookson and Co.

On Thursday evening a *Conversazione* was held at Armstrong College by invitation of the Newcastle Section.

Friday was devoted to a whole-day motor excursion up the Derwent Valley to Blanchland, thence to the Tyne Valley and Roman station at the Chesters, returning along the Roman Wall.

EXHIBITION.

During the week there was an interesting exhibition in Armstrong College of chemical and metallurgical products, apparatus, etc., mostly of local manufacture.

London Section.

Meeting held at Burlington House on May 3, 1920.

MR. JULIAN L. BAKER IN THE CHAIR.

THE THEORY OF GAS SCRUBBING TOWERS WITH INTERNAL PACKING.

BY F. G. DONNAN AND IRVINE MASSON.

The object of this paper is to obtain as simply as possible mathematical expressions which might serve as a preliminary basis for the experimental study of the factors which govern the design and operation of internally packed gas-scrubbing towers. It is hoped in later papers to present not only the results of this experimental investigation, but also a similar treatment of plate towers and other types of gas-washing plant.

In the relatively scanty literature on the theory of gas-scrubbing, the pioneering work of Dr. Ferdinand Hurter occupies a prominent position. In a series of papers communicated to this Society in the period 1885–1893¹ he stated an essential factor which governs the design of any apparatus wherein gas and liquid interact, and recorded many valuable experiments which afford fundamental data. The factor referred to is the area of gas-liquid interface offered per unit of volume of gas per unit of time; and on this basis he discussed the relative advantages of systems of bubbling, spraying, and tower packing. Thus Hurter's work is mainly concerned with the achievement of the maximum contact-time efficiency, irrespective of the solubilities and other specific properties of the gases and liquids which may be dealt with.²

Some time after the present paper had been written, we noticed that the theory of gas-absorption in packed towers had been dealt with by Partington and Parker,³ who applied it to the special case of the absorption of nitrous gases by dilute nitric acid. These authors took into account the fact that the dissolution of a gas in a liquid is not instantaneous, and they assumed that the rate of absorption is proportional to the concentration of the unabsorbed gas in the gas phase, which progressively diminishes from the bottom to the top of the tower. The equation deduced was:—

$$\text{Log}_e \frac{c_0}{c} = \frac{KkA}{V} x$$

where c_0 = initial concentration of the entering gas, c = its concentration at a height x in the tower, A = cross section of tower, V = rate of gas flow, k = area of packing surface exposed per unit of volume of tower, and K = a coefficient—not constant—depending on the rate of absorption of the gas by the liquid concerned, as found by experiment. The case is a special one, in that the change in absorption capacity and in rate of absorption of dilute nitric acid, due to nitrous gases which it has already absorbed, is slight and can be approximately allowed for. In other cases, however, this simplification is inadmissible, for the rate of solution of a gas in a liquid depends on the degree of unsaturation existing at the moment, as is well shown by the work of Adeney and Becker⁴ on the rate of solution of nitrogen and oxygen in water. The experimental results obtained by Adeney and Becker can be put into the following form. Let,

¹ J., 1885, 639; 1887, 707; 1889, 861; 1893, 227, 989.

² Some of the principles underlying the design of tower packing are set forth in an article published in "Chemical Engineering and The Works Chemist" (May, 1918).

³ J., 1919, 757.

⁴ Proc. Royal Dublin Soc., 1918-19, 15 (N.S.), 385, 609.

In order to integrate these equations, it is necessary to find the relation between m and n .

Since we may consider the level x as the bottom of a shorter tower, we have

$$V_g(m - M_2) = V_l(n - N_1) \quad \dots \quad (6)$$

and therefore

$$\begin{aligned} n &= \frac{V_g}{V_l} m - \left(\frac{V_g}{V_l} M_2 - N_1 \right) \quad \dots \quad (7) \\ &= f m - (f M_2 - N_1) \end{aligned}$$

substituting this value of n in equation (4), we have

$$\frac{dm}{dx} = \frac{k_1 k_2 S}{V_g} \left\{ (k-f)m + (f M_2 - N_1) \right\} \quad \dots \quad (8)$$

$$\text{or} \quad \frac{dm}{(k-f)m + (f M_2 - N_1)} = \frac{k_1 k_2 S}{V_g} dx$$

whence

$$\text{Log}_e \left\{ (k-f)m + (f M_2 - N_1) \right\} = \frac{k_1 k_2 S}{V_g} (k-f)x + \text{const.} \quad (9)$$

Now for $x=0$, $m=M_2$
and for $x=h$, $m=M_1$.

The first limiting condition shows that $\text{const.} = \text{Log} (k M_2 - N_1)$ so that:—

$$\text{Log}_e \frac{\{(k-f)m + (f M_2 - N_1)\}}{k M_2 - N_1} = \frac{k_1 k_2 S(k-f)}{V_g} x \quad \dots \quad (10)$$

The second limiting condition gives the equation:—

$$\text{Log}_e \frac{\{(k-f)M_1 + (f M_2 - N_1)\}}{k M_2 - N_1} = \frac{k_1 k_2 S(k-f)h}{V_g} \quad \dots \quad (11)$$

Subtracting (11) from (10) we have:—

$$\text{Log}_e \frac{\{(k-f)m + (f M_2 - N_1)\}}{(k-f)M_1 + (f M_2 - N_1)} = \frac{k_1 k_2 S(k-f)}{V_g} (x-h) \quad (12)$$

For given values of V_g , M_1 , M_2 , and N_1 equation (11) gives the relation between V_l , S , and k , or if V_g , M_1 , M_2 , N_1 , S , and h , are specified, we can calculate from this equation the value of V_l . Or again, if V_g , S , and h are specified (assuming $N_1=0$), we can determine the value of V_l required for any given value of r .

If, as will often be the case, $N_1=0$, we can write

$$\text{Log}_e \frac{(k-f) + f M_2}{k M_2} = \frac{k_1 k_2 S(k-f)}{V_g} x \quad \dots \quad (10')$$

$$\text{Log}_e \frac{(k-f)M_1 + f M_2}{k M_2} = \frac{k_1 k_2 S(k-f)h}{V_g} \quad \dots \quad (11')$$

and

$$\text{Log}_e \frac{(k-f)m + f M_2}{(k-f)M_1 + f M_2} = \frac{k_1 k_2 S(k-f)}{V_g} (x-h) \quad \dots \quad (12')$$

Equation (11') can be written in the form:—

$$\text{Log}_e \frac{k-f(1-r)}{kr} = \frac{k_1 k_2 S(k-f)h}{V_g} \quad \dots \quad (13)$$

If we also assume that M_2 is zero or negligibly small, equation (12') can be written in the simple form

$$\text{Log}_e \frac{m}{M_1} = \frac{k_1 k_2 S(k-f)}{V_g} (x-h) \quad \dots \quad (14)$$

$$\text{or} \quad m = M_1 e^{-\frac{k_1 k_2 S(k-f)}{V_g} (h-x)} \quad \dots \quad (15)$$

If the liquid issuing from the base of the tower be in equilibrium with the entering gas, then (if $N_1=0$)

$$\begin{aligned} V_g(M_1 - M_2) &= V_l k M_1 \\ \text{or} \quad \frac{V_l}{V_g} &= \frac{1-r}{k} \quad \dots \quad (16) \end{aligned}$$

Integration of equation (5) leads to similar equations relating m with x , namely:—

$$\text{Log}_e \frac{\frac{k-f}{f} n + k \left(M_2 - \frac{N_1}{f} \right)}{k M_2 - N_1} = \frac{k_1 k_2 S}{V_g} (k-f)x \quad \dots \quad (17)$$

$$\text{Log}_e \frac{\frac{k-f}{f} N_2 + k \left(M_2 - \frac{N_1}{f} \right)}{k M_2 - N_1} = \frac{k_1 k_2 S}{V_g} (k-f)h \quad \dots \quad (18)$$

If $N_1=0$, then equation (17) reduces to

$$\text{Log}_e \frac{\frac{k-f}{f} n + k M_2}{k M_2} = \frac{k_1 k_2 S}{V_g} (k-f)x \quad \dots \quad (19)$$

It will be observed that the equations given above reduce to identities if the factor $(k-f)$ be zero. The explanation of this is simple. Consider equation (2), i.e. $V_g \delta m = V_l \delta n$. If gas and liquid be in absorption-equilibrium at every level, then $n=kn$ and $\delta n=k \delta m$. Hence

$$V_g \delta m = k V_l \delta m, \text{ or } k = \frac{V_g}{V_l} = f.$$

But the supposition that gas and liquid are in absorption equilibrium at every level involves the conclusion that no interchange of the absorbable constituent occurs in the tower. For absorption to occur we must have $n < km$.

The aid which it is hoped these equations may ultimately afford in the design of towers to produce a predetermined effect may be briefly indicated by reference to equation (13), i.e.

$$\text{Log}_e \frac{k-f(1-r)}{kr} = \frac{k_1 k_2 S(k-f)h}{V_g}$$

Suppose we have to handle a given flow of gas V_g . Choice of temperature and solvent fixes k . If the tower is to be designed to effect a given ratio of absorption, say 0.01, then $r=0.01$. Choice of a certain flow of liquid and a certain type of packing leads to the fixing of f , k_1 , and k_2 . We are then left with S and h , which are now subject to the relation $Sh = a$ predetermined value. Practical considerations would then determine suitable values of S and h . We can certainly never expect to include all the varying conditions of practice in a simple set of algebraic equations.* But we may hope to employ such equations as a *guide* to practice as fully and as discreetly as the civil, mechanical, or electrical engineer employs his equations to guide him in the design of a bridge, a steam-turbine, or a dynamo. No attempt has been made in this paper to discuss different types of tower packing and their relative merits. Attention has been concentrated on the general physico-chemical principles governing the operation of scrubbing-towers in a specified simple case, with the object of obtaining a preliminary scientific basis for the subsequent treatment of questions of design.

It may suffice for the present to point out that the present paper shows in a quantitative manner how a high absorption efficiency depends on:—

- (a) High interfacial area between gas and liquid.
- (b) High relative motion of gas and liquid (within limits).
- (c) High degree of turbulent motion in one or both phases.
- (d) Sufficient rate of flooding to secure the maximum drip effect.

Chemical Laboratories,
University College, London.

DISCUSSION.

Dr. R. LESSING said that some means must be found for arriving at an expression for viscosity. In scrubbing coal gas with oil viscosity was of

*Frequently heat effects and temperature changes will play a prominent part. In this initial survey of the theory we have assumed that by suitable means the temperature is kept constant.

great importance, especially in its relation to subdivision and the turbulence to be effected. To make k , as large as possible a certain smallness of the filling body was necessary, particularly if the mass of the bodies was to be considered. It was essential that the total volume of the tower packing should be reduced to the minimum. That could only be done when the mass of the packing bodies was of small cubic capacity. For instance, if solid spheres of equal size were packed into a tower, 74% of the total capacity of the tower would be taken up by the solid material. In modern packings the idea was to reduce the amount of solid matter unapproachable by the liquid or gas and increase the surface between the packings. Raschig rings had the advantage that they occupied an exceedingly small proportion of the total volume of the tower; if made of ordinary sheet metal the standard 1-in. rings only occupied 7–9%, if of clay or acid-resisting material or cast iron 16–20%. They were disposed indiscriminately in the tower, and according to the angle formed between adjoining rings the cross-section of the open space between them varied. The descending liquid only had a certain small drainage space at its disposal without being stopped, and it was at that point that viscosity played a very considerable rôle. He had therefore designed another type of ring, which he had found to be very efficient both as regards total surface and drainage capacity. Unless the liquid running down the tower had a good drainage there would be stoppages, and back pressures would be set up which had a vital bearing on the gas stream outside the tower. To minimise back pressure on the gas he had designed a ring of circular shape with a centre partition which did not touch the opposite side of the circumference, nor was the circumference quite complete, so that there was at these places a considerable opportunity for drainage of the liquid. Had the authors considered that there might be a critical point at which turbulence might be excessive, i.e., that at that point the release of the dissolved gas from the liquid might be equally facilitated, as was the absorption of that same gas? To release the gas by heating, the same methods could be employed, and, supposing that a tower of this kind were designed which gave the highest possible efficiency at the top and at the bottom, then somewhere near the centre there must be equilibrium. He suggested that distillation or fractionation might be drawn within the sphere of calculation in connexion with solubility. He could not say whether that problem would be simpler or more complex. Using packed aggregates such as he had mentioned the results with fractionation were even more striking than with absorption of gases in liquids. He had been able to obtain fractionations with small rings which were better than the best obtained with Young's evaporative still-head. If it were possible to do this on the large scale, and to use these smaller bodies, the efficiency would be enormous and very small total tower capacities could be used. The 1-in. rings had 65–70 sq. ft. of surface per cu. ft., whereas the smaller rings had about 275 sq. ft. per cu. ft.

Prof. PARTINGTON said that the authors had attempted to take account not only of the differential rate of flow, which Dr. Parker and he had done in their paper, but of the change of concentration of the liquid throughout the tower. That had been introduced by Sorel before Dr. Parker and himself had done their work on the subject. They did not, however, take that into account, because in practice in nitric acid towers there was very little change of concentration of the liquid in passing through the tower. The rate of circulation was so high that the liquid had much the same composition throughout the tower. The most important factor in these equations was the absorption coefficient, i.e., the weight of soluble matter

absorbed from the gas in a given time by a given surface of liquid of given composition. The authors had attempted to bring that into line with the Henry coefficient. In practice, of course, the Henry coefficient did not apply to many cases, since the solubility of a gas was not proportional to its partial pressure, unless the gas was sparingly soluble. Dr. Parker and himself had considered that and had decided to abandon the use of Henry coefficients for that reason and to unite in one coefficient a number of these different separate variables. Theoretically it was very desirable to have these variables separated; but, as already pointed out, this absorption coefficient depended on turbulence, on the concentration of the gas and liquid, and so on, and his own case was complicated still further by the fact that chemical action took place in the liquid and an insoluble gas was again emitted. Nevertheless, by some work of Dr. E. K. Rideal, which had been suggested by Prof. Donnan, they had found that by suitable calculations it was possible to get a practical absorption coefficient which would apply to various fixed concentrations of liquid. All that was required to be known was the concentration of the acid in the tower, and that was fairly well fixed in a series of nitric acid towers. Then it became interesting to find by calculation if their simple equations would reproduce in any way the actual practical towers which were in use in various places, and, as they showed in their paper, it was possible to calculate the capacity of an absorption plant for the arc process such as was used in Italy with very great accuracy. Since that paper had been published, Dr. Parker had considerably extended the method of calculation and had obtained results which were quite close to those obtained in practice, including the new practice in French factories.

Captain C. J. GOODWIN pointed out that the authors had assumed throughout the paper that the rate of flow of liquid down the tower would be constant. In a great many cases that was not so. The modern tendency was not to have a steady rate of flow for the liquid, but to resort to periodical flushing, and he suggested that the authors should deduce from their formulæ the necessary coefficients for a tower in which it was assumed that the liquid retained on the surface of the packing was renewed or nearly renewed at each flushing, the quantity of liquid delivered each time corresponding approximately to that held on the wetted surface of the packing. In regard to direction of gas flow, it was generally assumed that contraflow must be more efficient than parallel flow. In some cases it was not so. With parallel flow of liquid and gas the time of contact was increased, and subject to considerations of the densities of the gases under treatment an improved efficiency was often obtainable by using parallel flow. The crux in the design of towers was the correct proportioning of scrubbing surface relatively to the maximum amount of free space economically permissible. Maximum scrubbing surface was not so important in reaction towers as distinct from absorption towers, because beyond certain limits an increase in scrubbing surface was useless if the rate of absorption exceeded the rate of formation of the substance to be absorbed.

Mr. W. MACNAE said that much work had been carried out during the war in various Government factories, and they had generally worked with 50% of free space in the absorption towers. The amount of nitrogen peroxide which was found to give the best results was 1 lb. per minute per 120 cu. ft. of free space when the surface area was 5000 sq. ft. Very uniform results were obtained over a long period of time in this way. That was working with 4000 Accrington earthenware rings of 3-in. size per tower. It was impracticable to fill up the large number of towers that had to be dealt with, with the

smaller rings mentioned by Dr. Lessing, on account of the expense.

Mr. H. GRIFFITHS observed that one of the fundamental assumptions in the paper was that the temperature remained constant throughout the tower. This was not always so in practice, and if the theory were applied in some cases the error would be very serious. In the case of hydrochloric acid it would easily be possible to feed cold water into the top of the tower and have a boiling solution issue at the bottom; in fact the boiling point would be reached even with as low a concentration as about 13% HCl. The authors had also assumed that the absorbing liquid was simply allowed to trickle through the tower, whereas in practice it was exceedingly common to employ a much larger circulation, and to pump the liquid from the bottom outlet N_2 and return to the tower at the top N_1 , a small portion only being short circuited to allow for the feed. Dr. Partington (*loc. cit.*) had taken this practice into account. Occasionally, in order to control the temperature within the tower, additional cooling surface would be added in the liquid circuit outside the tower. The constant k , had become a sort of accepted basis for judging the relative efficiencies of the various packings, but comparative tests showed that the various patent packings for which high values of surface per cubic foot could be secured, and for which in consequence high efficiencies were claimed, did not function so satisfactorily. This was probably because these packings consisted of a fairly dense arrangement of materials of low thermal conductivity, and the dissipation of heat of reaction from the tower was hindered. He had been told that in past years it was customary in the case of nitric acid towers to express the data for design in terms of lb. of nitric acid per hour per sq. ft. of radiating surface of the tower, therein taking account only of the thermal effect in the tower.

Dr. PARKER enlarged upon the point raised by Captain Goodwin with regard to the space left for reactions to take place in the tower which was unoccupied by the packing material. In the paper communicated by Dr. Partington and himself they were there only concerned with the reactions involving the formation of nitric acid in water absorption towers; one of the most important of these was the reaction between nitric oxide and atmospheric oxygen for the formation of nitrogen peroxide, in the absence of which no nitric acid could be formed in the absorbing liquid. From practical experience he could say that there were plants in operation in which there was from four to seven times more area exposed by the packing in the absorption towers than was necessary for the absorption of the NO_2 ; the result was that the efficiency of the absorption system was of the order of 70% instead of 90%, as claimed by the engineers in charge. It was very probable that the efficiency of absorption of such plants could be materially increased by a judicious unpacking of some of the towers, to leave more free space for the formation of nitrogen peroxide without decreasing the absorbing surface of the packing to such an extent as to inhibit the formation of nitric acid.

Mr. P. PARRISH said that for 20 years he had been designing towers in connexion with sulphuric acid manufacture, which offered very complex conditions, because the design of the Glover tower was dependent not only on the proportion of the chamber plant and the burners, but the capacity and effectiveness of the Gay-Lussac tower had a very important bearing on the operation of the Glover tower. Prof. Donnan decried the fact that there was not much data available with regard to the theory of absorption, but Hurter, 30 years ago, had given a really remarkable exposition of the theoretical considerations underlying absorption. Little practical data was available for use or appli-

cation by the practical chemical engineer. For 15 years the only data that the chemical construction engineer had had in connexion with the design of the Glover tower in connexion with sulphuric acid plants was that for every ton of sulphur burned daily in the form of pyrites it was necessary to have 550 cb. ft. of Glover tower capacity. That paid no regard to mass, to available surface area, or to the effective scrubbing surface per cubic foot. Some two years ago, as the result of designing some 50 towers in connexion with sulphuric acid plant, he had attempted to correlate the theoretical and the practical data which he had been able to amass. In regard to the design of Glover towers, in so far as they affected the manufacture of sulphuric acid, he had come to the conclusion that it was essential to afford 4½ sq. ft. of surface area per ton of monohydrate sulphuric acid made per day at a point in the tower where the lining of the tower was not more than 9 in. He had then developed in connexion with 10 different types of packing the free space per cb. ft., the superficial free space per sq. ft., the inlet area required, and the scrubbing surface in sq. ft. per cb. ft., and as a result of these considerations he had found that in many cases Glover towers had been over-designed to the extent of 300%, and in some cases towers were operating which were 500 and 600% more than was theoretically necessary. There were quite a number of other considerations in the functions of a Glover tower apart from absorption. In the first place, in the lower portion of the Glover tower concentration primarily occurred. Denitration also was effected, and such denitration took place within very narrow and well-defined limits. Assuming that the tower was over-designed, abnormal quantities of sulphuric acid were formed to the extent of from 10 to as much as 40% of the total make. It was very difficult to say precisely the point at which concentration ceased and denitration commenced, and the point at which denitration left off and making commenced, and the correlation of the various parts constituting a sulphuric acid plant must be taken into consideration both in connection with Glover towers and Gay-Lussac towers. The tendency in the future so far as absorption and reaction under the conditions he had outlined were concerned would be not so much reaction between gas and liquid *via* a medium which afforded a sort of skin friction, but to have a bubbling of the inter-phase—gas and liquid. He referred particularly to the Kessler type of plant. In this the material of which the calottes were made would not stand the stringent conditions to which they were subjected, and resort had to be had eventually to a filling medium. Experience of the working of the Kessler plant under the modified conditions suggested that the future tendency would be in the provision of some arrangement which admitted of actual bubbling of the gas through the liquid medium in order to reduce the limits and dimensions of the plant, concurrently reducing the capital expenditure thereon.

Dr. W. R. ORMANDY mentioned that he had recently designed a certain absorption tower in which the air carrying the small amount of soluble matter entered the bottom practically cold and in which no chemical reaction took place. He had no data to go upon, and so had allowed a large factor of safety and then doubled it. He believed that this tower would provide Prof. Donnan with exactly the data he required in order to build a theory.

Dr. IRVINE MASSON, in reply, said that the authors regretted they had had to leave aside for the moment those very interesting and perhaps more important kinds of tower where chemical reactions were performed. In these were included Glover towers, Gay-Lussac towers, and NO_2 towers. Even then, however, there were many applications of scrubbing towers where a simple physical kind of solution had to be brought about, and it was to

these that attention had first been directed. The simplifying assumptions, which had been justly commented on, were made with the idea he had mentioned. For instance, the thermal effect due to the condensation of any vapour or gas must always be taken into account in designing a tower, but as a beginning a theory for an isothermal process was needed. An equation was wanted to start with which could be elaborated factor by factor, and the thermal effect was one of these which would naturally be brought in as soon as possible, but it had not yet been done. The paper by Dr. Partington and Dr. Parker had given the first quantitative expression to be actually published, and as such it must receive great attention. It was to be noted that the assumptions made by Dr. Partington referred to the special case of nitric acid, which was not matched by any of the simple cases of physical solution which the authors of the present paper were considering. The essential difference, mathematically speaking, between the special case discussed by Dr. Partington and the one dealt with in this paper was the introduction of the factor $k-f$. It was necessary to take account of the fact that not only did the liquid absorb gas, but the gas tended to come out again. The rate of solution of the gas in a liquid surface per unit area per unit of time was proportional to the degree of unsaturation of that liquid, which depended not only on the concentration in the gas phase itself, but on the concentration of the gas already absorbed in the liquid. That was not the case in the investigation by Messrs. Partington and Parker.

Dr. PARTINGTON: We allowed for that in the calculation.

Dr. MASSON agreed that Messrs. Partington and Parker's factor k , obtained by experiments, empirically covered effects of this nature in the case dealt with; Professor Donnan and he had not done such experiments, but had attempted a generalised solution of the problem by the use of the Henry constant k and the variable factor k_2 .

Manchester Section.

Meeting held at Grand Hotel on May 7th, 1920.

MR. JOHN ALLAN IN THE CHAIR.

HYDROGENATION IN THE NAPHTHALENE SERIES.

BY F. M. ROWE, M.Sc., A.I.C.

In the course of the investigation of the reducing action of sodium and an alcohol carried out by Bamberger and his collaborators, hydro derivatives of naphthalene, the naphthylamines, naphthols, aminonaphthols, and naphthylenediamines were prepared. The products are invariably tetrahydro derivatives when sodium and amyl alcohol are used, but in the case of naphthalene itself the use of ethyl alcohol results in the formation of the dihydro derivative. The yield and character of the reduction product vary with the individual substance reduced, for α -derivatives of naphthalene give rise mainly to aromatic (ar.) compounds, whilst β -derivatives form mainly alicyclic (ac.) compounds. The aromatic compounds contain the additional four hydrogen atoms in the unsubstituted ring, and possess an accentuated benzenoid character, whilst the alicyclic compounds, which contain the additional four hydrogen atoms in the substituted ring, have lost their aromatic character and assumed the characteristics of an aliphatic compound.

The attention of subsequent investigators has been devoted mainly to the further examination of ar-tetrahydro- α -naphthylamine and its derivatives, for the action of sodium and amyl alcohol on α -naphthylamine results in the formation of this base more readily and in a better yield (70% of the theoretical) than is the case when other derivatives of naphthalene are submitted to the same reaction.

Ar-tetrahydro- α -naphthylamine has been shown to possess many interesting properties. It retains the naphthalenoid characteristic of reacting with diazonium salts under ordinary conditions, forming aminoazo compounds without the intermediate formation of diazoamines, in which respect it differs from ar-tetrahydro- β -naphthylamine, which forms intermediate diazoamines but does not form aminoazo compounds. In all other respects ar-tetrahydro- α -naphthylamine resembles a benzenoid amine, particularly γ -xylylene ($\text{CH}_3\text{:CH}_2\text{:NH}_2$ 1:2:3).

Of further interest is the fact that azo dyes derived from ar-tetrahydro- α -naphthylamine and its derivatives differ considerably in shade from similar azo dyes derived from α -naphthylamine and its derivatives (Bamberger, Ber., 1887, 20, 2915; Bamberger and Bordt, Ber., 1889, 22, 625; Morgan and Richards, J., 1905, 652; Green and Rowe, Chem. Soc. Trans., 1918, 113, 955; Rowe, J. Soc. Dyers and Col., 1919, 35, 128), approximating in this respect to dyes derived from benzenoid amines.

As a result of these investigations it is clear that ar-tetrahydro- α -naphthylamine and its derivatives might well prove useful intermediate products to the manufacturers of dyes if the production of the base on a technical scale were economically possible.

The conditions governing the formation of the base therefore were examined more closely. Bamberger refers to the influence of the particular alcohol used in the reduction on the yield and constitution of the reduction product, for tetrahydro-naphthalene is formed when an amyl alcoholic solution of naphthalene is reduced with sodium, but dihydronaphthalene is formed when amyl alcohol is replaced by ethyl alcohol. Further, in the case of β -naphthylamine, the replacement of amyl alcohol by ethyl alcohol results in a minimum yield of the tetrahydro derivative. It was concluded that the course taken by the reaction and the yield obtained was intimately connected with the boiling point of the solvent employed, but the later experiments of Bamberger and Muller (Ber., 1882, 21, 1112), using such solvents as hexadecyl alcohol, phenol, glycerol, and mixtures of amyl alcohol and vaseline, did not support this hypothesis, at least in the case of β -naphthylamine.

When a boiling solution of α -naphthylamine in ethyl or butyl alcohol is treated with sodium no tetrahydro base is formed, whilst the addition of butyl alcohol to amyl alcohol produces a diminution in the yield of ar-tetrahydro- α -naphthylamine proportional to the quantity of butyl alcohol in the mixture. Moreover, in an experiment in which butyl alcohol was employed under a pressure sufficient to raise the boiling point to that of amyl alcohol under normal pressure no tetrahydro base was formed, though as the apparatus used in this experiment burst, it is possible, in the light of later experiments, that the reaction had not proceeded for a sufficient length of time to produce the desired result.

At the time it appeared that this difference in the behaviour of amyl alcohol from that of other alcohols was not due merely to differences in boiling point, and as the reaction was always accompanied by a destruction of 10–15% of the amyl alcohol used, it seemed possible that the reduction was intimately connected with this oxidation of amyl alcohol, and was not simply a direct hydrogenation to the tetrahydro compound.

In the course of these experiments it was noted that when butyl alcohol was used the melting point of the base was lowered, but as no tetrahydro base

was formed, this point was not investigated further at the time. Recently, however, experiment has shown that this lowering of the melting point is due to a partial conversion of the α -naphthylamine into dihydro- α -naphthylamine.

The effect of the presence of various catalysts on the reaction with sodium and a butyl alcoholic solution of α -naphthylamine was studied also, but in no case could the presence of the tetrahydro base be detected after reduction.

According to the patents of F. Bayer und Co. (G.P. 305,347 and 306,724), alkali and alkaline-earth metals and alcohols, such as ethyl alcohol, reduce isocyclic and heterocyclic bases in the presence of "indifferent solvents." It is stated that ar-tetrahydro- α -naphthylamine is formed when an alcoholic solution of α -naphthylamine is added to a mixture of solvent naphtha and sodium at a temperature above 130° C., but that when an indifferent solvent of lower boiling point, such as toluene, is used, dihydro- α -naphthylamine is obtained. Consequently it would appear that ar-tetrahydro- α -naphthylamine is formed when α -naphthylamine, dissolved in any alcohol, is added to a boiling mixture of solvent naphtha and sodium, and that replacement of solvent naphtha by toluene results in the formation of dihydro- α -naphthylamine, irrespective of the alcohol used. If such were the case, the important factor in the reaction is obviously the temperature at which the reduction is carried out and the nature of the alcohol used is immaterial.

In order to test this point a series of comparative experiments was carried out, in which 30 g. of sodium was covered with 400 c.c. of an indifferent solvent, raised to the boiling point, and a solution of 34 g. of α -naphthylamine in sufficient alcohol to dissolve the sodium was added slowly, the mixture being worked up as soon as all the sodium had disappeared. Under these conditions ar-tetrahydro- α -naphthylamine was formed only when amyl alcohol was used, and was produced equally well at the boiling point of toluene as at the boiling point of solvent naphtha (139° C.), whilst when ethyl or butyl alcohol was substituted for amyl alcohol, dihydro- α -naphthylamine was formed even at the boiling point of solvent naphtha. Further, when dihydro- α -naphthylamine was substituted for α -naphthylamine and treated with sodium, ethyl alcohol, and solvent naphtha as before, it remained unaffected by the treatment. It is clear, therefore, that some other factor is concerned in the reaction besides the temperature at which it is carried out.

This method of preparation is, nevertheless, an improvement on Bamberger's method for the preparation of ar-tetrahydro- α -naphthylamine, for it requires less than one-third of the quantity of alcohol previously necessary; it is more convenient to cover sodium with an indifferent solvent and to add an alcoholic solution of α -naphthylamine to the boiling mixture than to add sodium in several portions to a boiling alcoholic solution of α -naphthylamine; and further, by replacing amyl alcohol by another alcohol, the previously unknown dihydro- α -naphthylamine is obtained. In fact, as far as the preparation of hydrogenated naphthalene derivatives by means of sodium and an alcohol is concerned, it is doubtful whether this method can be improved upon.

The constitution of the dihydro- α -naphthylamine obtained in these experiments was next investigated by removing the amino group so that the corresponding dihydronaphthalene could be examined and identified. The literature with regard to dihydronaphthalene is rather involved for the following reasons:—

(1) It has not always been recognised that two isomers exist, viz., 1,4-dihydronaphthalene and 1,2-dihydronaphthalene, the former yielding

phenylene-diacetic acid and the latter hydrocinnamic-*o*-carboxylic acid on oxidation.

(2) The melting points of the dibromides of the two isomers, which have been used for their identification, lie close together, being 71.5°–72° C. and 70°–71° C. respectively. (Actually when these compounds are compared with one another they may be readily distinguished, for the former crystallises in long, glittering, thin prisms, while the latter forms stout prismatic crystals; a methyl alcoholic solution of the former remains neutral after prolonged boiling, whilst with the latter the solution reacts strongly acid after short boiling; the melting point of either is lowered by admixture with the other.)

(3) The dihydronaphthalenes form mixed crystals with naphthalene which cannot be separated completely by physical means. These mixed crystals melt considerably higher than the pure dihydronaphthalene.

Experiments which were carried out with the dihydronaphthalenes in order to check their properties confirmed the work of Straus and Lemmel (Ber., 1913, 46, 232).

Crude 1,4-dihydronaphthalene, prepared by the method of Bamberger and Lodter by the action of sodium and ethyl alcohol on naphthalene (Annalen, 1895, 288, 75), was purified as described by Sand and Genssler (Ber., 1903, 36, 3705) by shaking an ethereal solution with an aqueous solution of mercuric acetate for 24 hrs. The crude mercury compound which separated was extracted with boiling benzene in a Soxhlet and crystallised in colourless needles, m.p. 121° C., which when decomposed with hydrochloric acid yielded pure 1,4-dihydronaphthalene, crystallising in plates, m.p. 24.5°–25° C.

The isomeric 1,2-dihydronaphthalene was first obtained by heating 1,4-dihydronaphthalene with five times its volume of 5% sodium ethoxide at 140°–150° C. for 8 hrs., but it was subsequently shown by Straus (Ber., 1913, 46, 1051) that both the temperature and concentration of the sodium ethoxide employed play a part in this reaction. When 1,4-dihydronaphthalene is heated with 5% sodium ethylate at its boiling point (87° C.) for 1 hr., there is no conversion, whilst a two-thirds conversion occurs at 105° C., and at 140° C. heating for $\frac{1}{2}$ hr. is sufficient for complete conversion. On the other hand, by using 10% sodium ethoxide the conversion is complete after heating at 100°–105° C. for 1 hr. The latter method was used for the preparation, except that it was found convenient to allow the alcohol to distil slowly during the reaction. In order to ensure purity, the product was converted into the mercury compound by shaking an ethereal solution with aqueous mercuric acetate, the product extracted with boiling benzene, in which the mercury compound of 1,2-dihydronaphthalene is insoluble, and decomposed with hydrochloric acid. Pure 1,2-dihydronaphthalene crystallises in colourless plates, m.p. –9° C.

There is no doubt that, in all investigations in which dihydronaphthalene has been prepared by the elimination of water, ammonia, hydrochloric acid, etc., from alicyclic derivatives of tetrahydronaphthalene and identified by means of the dibromide, the compound was actually 1,2-dihydronaphthalene and not 1,4-dihydronaphthalene as was supposed.

An important difference in properties between 1,4- (I.) and 1,2-dihydronaphthalene (III.) is that only the latter compound is reduced to tetrahydronaphthalene by sodium and ethyl alcohol. This fact disposed of the difficulty of reconciling the reduction of naphthalene through 1,4-dihydronaphthalene to tetrahydronaphthalene with the

behaviour of the analogous allylbenzene (II.) and propenylbenzene (IV.)—

only the latter of which is reducible by sodium and an alcohol to a saturated homologue of benzene, and consequently 1,4-dihydronaphthalene should not be directly reducible.

The preparation of tetrahydronaphthalene by Bamberger and Kitchelt by the action of sodium and amyl alcohol on naphthalene (Ber., 1890, 23 1561) is, therefore, explained by the initial formation of 1,4-dihydronaphthalene followed by isomerisation to the 1,2-dihydro compound and the formation of tetrahydronaphthalene under ordinary conditions only when amyl alcohol is used in the reduction and not when other alcohols are used, must be due to the fact that only in the former case are the concentration of sodium alkoxide and the temperature suitable for the isomerisation of the 1,4-dihydro derivative prior to further hydrogenation. The dihydronaphthalene obtained from the dihydro- α -naphthylamine previously referred to proved to be the 1,4- isomer and consequently the amino is 5,8-dihydro-1-naphthylamine. It crystallises in large colourless, rhombic plates or needles, m.p. 37°–38° C., and its hydrochloride crystallises in stout needles. The first stage in the reduction of α -naphthylamine, therefore, is similar to the first stage in the reduction of naphthalene, and if the two cases are completely analogous it is clear that this dihydro- α -naphthylamine would not be reduced to ar-tetrahydro- α -naphthylamine by a further treatment with sodium and ethyl alcohol, unless the conditions of the reaction were such as to bring about a preliminary conversion into the isomeric dihydro- α -naphthylamine by boiling with sodium ethoxide.

In order to test this hypothesis the reduction mixture employed for the preparation of 5,8-dihydro- α -naphthylamine was boiled for a number of hours after all the sodium had disappeared, instead of being worked up immediately. It was found that the reaction product was a mixture of two amines in this case and that by increasing the proportion of sodium employed or by using more concentrated sodium ethoxide and boiling for several hours, the whole of the 5,8-dihydro- α -naphthylamine was converted into this new amine. Further, this amine is readily reduced to ar-tetrahydro- α -naphthylamine by treatment with sodium and ethyl alcohol, even in the absence of a high boiling indifferent solvent. The hydrocarbon obtained from this base by removing the amino group proved to be 1,2-dihydronaphthalene, and consequently the amine is 5,6- dihydro- 1- naphthylamine or 7,8- dihydro-1-naphthylamine. It is a colourless oil, which does not solidify in a freezing mixture of ice and salt, and its hydrochloride crystallises in needles, whilst ar-tetrahydro- α -naphthylamine, which is also an oil, forms a hydrochloride which crystallises in pearly plates. It condenses with diazonium salts, forming aminoazo compounds, and when diazotised and coupled with amines and phenols it forms azo dyes.

The further investigation of the isomeric dihydro- α -naphthylamines is at present in progress.

The course of the reaction in the formation of ar-tetrahydro- α -naphthylamine from α -naphthylamine by the action of sodium and an alcohol is completely analogous to the conversion of

naphthalene into tetrahydronaphthalene, the first stage being the formation of 5,8-dihydro-1-naphthylamine, which is isomerised to the 7,8-compound, this latter then being reduced to the tetrahydro derivative.

Apparently the reason why ar-tetrahydro- α -naphthylamine has been obtained in the past only when amyl alcohol has been employed, and not when other alcohols have been used, is that only in the former case have the normal conditions of the reaction been suitable for the isomerisation of the intermediate 5,8-dihydro- α -naphthylamine.

It seemed desirable now to investigate more closely the direct hydrogenation of naphthalene and its derivatives by means of hydrogen in presence of a catalyst.

Sabatier and Sonderens, who prepared cyclohexane by passing a mixture of benzene and hydrogen over finely divided nickel at 180°–200° C. (Comptes rend., 1901, 132, 210), found that tetrahydronaphthalene was formed from naphthalene by a similar treatment at 200° C. (*ibid.*, 1901, 132, 1254). Ipatiev obtained successively tetrahydro- and decahydro-naphthalene by heating naphthalene with hydrogen in presence of nickel or its oxide at 250° C. under 120 atm. pressure, and α - and β -naphthol were converted in a similar manner into the corresponding decahydronaphthols. Willstätter and Hatt obtained perhydro- and decahydro-naphthalene by shaking an ethereal or glacial acetic acid solution of naphthalene with platinum black and hydrogen in a closed vessel (Ber., 1912, 45, 1474), whilst Willstätter and King, using the same method, found that naphthalene did not form tetrahydronaphthalene at any stage of the process, but that a mixture of naphthalene and perhydro-naphthalene was always produced until all the naphthalene was converted into perhydronaphthalene (*ibid.*, 1913, 46, 527). The same authors, however, obtained tetrahydronaphthalene from pure dihydronaphthalene—prepared by the exhaustive methylation of ac-tetrahydro- β -naphthylamine—which they believed to be 1,4-dihydronaphthalene, but which was actually the 1,2-isomer.

A method by which Lebeau and Pichon obtained tetrahydronaphthalene in a 90% yield consisted in enclosing a mixture of liquefied ammonia, sodium, and naphthalene in an autoclave, and allowing it slowly to attain the air temperature (Comptes rend., 1914, 158, 1514). In this reaction the sodamide formed must influence the course of the hydrogenation, as nascent hydrogen alone does not convert naphthalene into tetrahydronaphthalene.

In the case of the hydrogenation of aromatic amines, Sabatier found that the products obtained by passing a mixture of aniline and hydrogen over nickel at 190° C. were ammonia, benzene, cyclohexane, cyclohexylamine, dicyclohexylamine, and cyclohexylaniline (Comptes rend., 1904, 138, 457); a mixture of 40–50% cyclohexylamine, 10% dicyclohexylamine, and 10% cyclohexylaniline was obtained by Ipatiev by heating aniline and hydrogen in presence of nickel at 220°–230° C. under a high pressure for 50 hours; and Willstätter and Hatt obtained dicyclohexylamine as principal product with only 10% of cyclohexylamine by shaking a glacial acetic acid solution of aniline with hydrogen in presence of platinum black in a closed vessel at the ordinary temperature (*loc. cit.*).

The reduction of α -nitronaphthalene to α -naphthylamine with an excess of hydrogen in presence of a catalyst at 330°–350° C. was examined by Sabatier and Senderens (Comptes rend., 1902, 135, 225), who found that copper was the most suitable catalyst, as nickel gave rise to the elimination of ammonia and formation of tetrahydronaphthalene.

With regard to this elimination of ammonia during the reduction of amines, the reaction is reversible under suitable conditions, for Meyer and Tanzen found that traces of aniline are formed

when a mixture of benzene and ammonia is passed over nickel at 550° C. (Ber., 1913, 46, 3184), presumably as the result of a simultaneous dehydrogenation of the ammonia and hydrocarbon. In order to determine whether naphthalene and ammonia behaved in an analogous manner we carried out some experiments in which a mixture of ammonia and naphthalene was passed over nickel at 300° C., and obtained a yield of about 2% of base which appeared to be a mixture of α -naphthylamine and 5,8-dihydro- α -naphthylamine, and hydrogen was detected. The reaction is probably:—

The possibility of simultaneous dehydrogenation occurring must be taken into consideration in attempts to hydrogenate naphthalene derivatives, for the addition of hydrogen to an unsaturated aromatic compound in the presence of a catalyst may be reversed under suitable conditions, leading to a state of equilibrium between the hydrogenated and dehydrogenated compounds. In view of the results already obtained in the catalytic hydrogenation of aromatic compounds and amines in particular, it was decided to employ a nickel catalyst deposited on kieselguhr for our experiments on the hydrogenation of α -naphthylamine and to carry out similar experiments with naphthalene, which might serve as a guide in the former case. The hydrogen employed was purified by passing through 40% caustic soda solution, concentrated sulphuric acid, a heated copper tube containing a roll of electrolytic copper gauze, and a U-tube containing moistened caustic potash.

The process adopted for the experiments, which should be regarded as preliminary and of a qualitative nature only, consisted in prolonged bubbling of hydrogen at the ordinary pressure through the purified substance, either molten or dissolved in a suitable solvent, in presence of nickel deposited on kieselguhr, in a glass vessel fitted with a condenser and an agitator capable of being driven at a high speed.

Temperatures varying from 100° C. to the respective boiling points were tried with naphthalene and α -naphthylamine, in the absence of solvents, without result, except that there was an appreciable evolution of ammonia in the latter case, particularly at the higher temperatures used.

Negative results were obtained also in the case of α -naphthylamine dissolved in such solvents as petroleum ether, toluene or solvent naphtha, the experiments being carried out at the boiling point of the solvent. The first positive results were obtained by using a boiling ethyl alcoholic solution of naphthalene, when it was found that hydrogenation occurred. Under the conditions used, the products obtained were invariably mixtures which, however, could be separated readily. The first main product of hydrogenation proved to be 1,4-dihydronaphthalene, and this appears to be the first instance of the preparation of a dihydro derivative in the naphthalene series by direct hydrogenation in presence of a catalyst. A more prolonged reaction, or treatment of 1,4-dihydronaphthalene in boiling ethyl alcoholic solution, led to the formation of some tetrahydronaphthalene together with a mixture of lower boiling liquids, which were not examined closely, but were probably the more saturated derivatives.

Hydro derivatives of naphthalene were of considerable importance in Germany during the war. Tetrahydronaphthalene or "tetralin" and decahydronaphthalene or "dekalin" are valuable solvents and motor fuels which are now available in Germany in large quantities, and are manufactured by the direct hydrogenation of naphthalene (Vollmann, *Farben-Zeit.*, 1919, 24, 1689). It is not within the scope of this present paper to emphasise the importance of hydrogenated derivatives of

naphthalene as motor fuels, but it should be noted that these compounds, whilst having approximately the same calorific value as naphthalene, are mobile liquids, and that there must be some stage in the hydrogenation at which the compound will burn like a fatty compound without deposition of carbon in the cylinder.

An investigation of these compounds from this point of view is at present in progress in collaboration with Captain F. S. Sinnatt, the results of which will be presented to this Society on some future date.

With regard to α -naphthylamine positive results were obtained also when the treatment was carried out in a boiling ethyl alcoholic solution, but the hydrogenation was more satisfactory when boiling mixtures of ethyl alcohol and toluene or ethyl alcohol and solvent naphtha were used.

In the latter case, the α -naphthylamine was completely converted into dihydro- α -naphthylamine by prolonged bubbling of hydrogen, the catalyst being replaced by a fresh portion half way through the reaction. Examination proved this compound to be 5,8-dihydro- α -naphthylamine. Attempts were made to convert this compound into ar-tetrahydro- α -naphthylamine by further treatment, but whilst there was evidence of some reduction taking place, under the conditions used, no satisfactory conversion occurred. In view of these preliminary results, an apparatus is being constructed which will allow the experiments to be carried out under an increased pressure, and when complete this investigation will be continued.

In conclusion, I wish to express my thanks to Miss E. Levin and Mr. S. Loo, who have carried out a large number of the experiments connected with this work, and to Messrs. British Dyestuffs Corporation (Blackley), Ltd., who have kindly supplied me with the sodium and α -naphthylamine required in this investigation.

DISCUSSION.

The CHAIRMAN said that the author's results indicated that a certain reaction proceeded much more efficiently in the presence of a copper than it did in the presence of a nickel catalyst, although, so far as was known, the mechanism in the two reactions was the same. If the mechanism were the same it would appear that the condition of the catalyst, the temperature at which it was operated, and the concentration in which it was used might play a very considerable part in the results. Very complex mixtures were obtained in the hydrogenation of naphthalene, and most of the products were obtained as the result of secondary reactions. By removing the desired product from the zone of reaction quickly it might be possible to control the results.

Professor PRYAN said that the naphthalene series was connected in a very simple manner with derivatives of isoquinoline. Now the reduction of isoquinoline and particularly of its derivative papaverine, had been studied pretty fully. Papaverine was an isoquinoline containing three substituents, methoxyl groups in the 6- and 7-positions, and a dimethoxybenzyl residue in the 1-position. Reduction of papaverine gave, to some extent, tetrahydropapaverine, and also a dihydropapaverine, but this was not analogous to anything Mr. Rowe had shown. It contained undoubtedly a bi-cyclic ring in the place of the pyridine ring, the 1- and 3-carbon atoms being united by a bridge, for when it was de-graded by suitable methods it gave derivatives of indene. This was perhaps interesting by way of contrast with the naphthalene series. In using sodium and alcohol in considerable quantities he found it con-

venient to employ the following method: The sodium was put in at the bottom of a large bolt head fitted with a reflux condenser and a dropping funnel and covered with a small proportion of the alcoholic solution, the whole being heated in an oil bath, and the bulk of the alcoholic solution was then introduced through the dropping funnel; by this means the reduction of considerable quantities was conveniently effected. Caro was necessary with amyl alcohol. Windans, who had worked a great deal with cholesterol, had shown that in this case the action of sodium and amyl alcohol did not simply effect reduction, but also addition of an amyl alcohol residue.

Mr. J. BADDILEY said that, within certain limits, there appeared to be an analogy between addition in the case of hydrogenation and substitution in the case of sulphonation of naphthalene. Apparently, in the hydrogenation of the naphthalene derivatives investigated, the reaction went through the *p*-dihydro compound to the *ortho*, just as in sulphonation the first-formed product was the α -acid which was then isomerised to the β -acid. In hydrogenation by means of sodium and alcohols the author had shown that only in the case of amyl alcohol did the hydrogenation pass beyond the dihydro stage. Further progress to the tetrahydro stage depended on the isomerisation of the 1,4-dihydro to the 1,2-dihydro compound. It was possible that whereas other alcohols had none, amyl alcohol had a specific isomerising effect, this difference being paralleled by the different isomerising effect of different strengths of sulphuric acid in the case of sulphonation. Had the author tried the effect of the presence of amyl alcohol in catalytic reductions? With regard to azo dyes he bore out what the author had said about the analogy between the behaviour of tetrahydro- α -naphthylamine and that of certain amines of the benzene series. In coupling with diazo compounds, however, *p*-xylylene presented a closer analogy than did *o*-xylylene.

Dr. T. CALLAN asked if the hydrogenated derivatives of the naphthylamines showed the same difference in their behaviour to nitrous acid, *e.g.* in the difficulty of obtaining clear diazo solutions and quantitative absorption of nitrous acid, as did the corresponding non-hydrogenated derivatives. Had the effect of traces of water on the reduction process been studied, and had other metals, such as calcium, been employed in place of sodium in the reduction process? Further, if the hydrogenated naphthylamine derivatives resembled the xylylenes in their characteristics, did they condense with benzaldehyde to form crystalline benzylidene compounds such as *p*-xylylene gave, or non-crystalline compounds such as the other xylylenes formed?

Captain F. S. SINNATT said that a compound of the nature of tetrahydronaphthalene which would have a fairly high calorific value and was a liquid should find a wide use as a fuel. The substance was no doubt easily soluble in alcohol, and if it would burn in the same manner as a fatty compound it could be added to alcohol to increase its calorific value.

Dr. J. A. R. HENDERSON remarked upon the difficulty in identifying the 1,2- and the 1,4-dihydronaphthalenes, and asked if the author had studied the action of chromyl chloride upon these two isomers. Chromyl chloride had been used with great success in the study of the constitution of the terpenes, and probably might serve to differentiate the dihydronaphthalenes.

Mr. W. A. SILVESTER said that in referring to the use of hydrogenated naphthalenes as motor-fuels the author had not stated the boiling-points of the compounds. They should be comparatively

high, and he had gathered that in Germany the compounds had been mainly applied as substitutes for lubricating oils. It was possible that the use of high temperatures in the Sabatier-Senderens process resulted in a cracking similar to that which occurred when petroleum hydrocarbons were heated.

Mr. Rowe, in reply, said that the secondary reactions which might take place in connexion with direct hydrogenation could not be better exemplified than in the case of the catalytic hydrogenation of aniline. Tetrahydroquinoline and tetrahydroisoquinoline were particularly interesting to him. The former closely resembled monomethylaniline in its properties and the latter benzylamine. The *N*-methyl derivative of tetrahydroquinoline resembled dimethylaniline, for it formed a *p*-nitroso derivative, and condensed with benzaldehyde to form an analogue of Malachite Green, whilst *p*-aminotetrahydroquinoline behaved like an alkylated *p*-phenylenediamine giving the Indamine, Safranin, and Methylene Blue reactions. As all his experiments on the direct catalytic hydrogenation of naphthalene had been qualitative only, up to the present time, no figures could be given as to the relative cost of tetrahydronaphthalene and other fuels. The analogy drawn by Mr. Baddiley between hydrogenation and sulphonation in the naphthalene series was interesting. Amyl alcohol had been tried in the experiments on catalytic hydrogenation, but as it took part in the reaction, resulting in a complex mixture of products very difficult to deal with, its use was abandoned. It was true that tetrahydro- α -naphthylamine, whilst resembling an *o*-xylylene in structure, more closely resembled a *p*-xylylene in properties. There was less difficulty in obtaining clear diazo solutions with tetrahydro- α -naphthylamine than with α -naphthylamine. He hoped to have more to say with regard to azo dyes derived from hydrogenated amines when work, at present in progress, was completed. The effect of the presence of traces of water on reduction with sodium and an alcohol had been studied. Dry alcohol was essential, for when naphthalene was reduced with 96% ethyl alcohol and sodium, a product was obtained melting at 37°–40° C. which was a mixture of 1,4-dihydronaphthalene with unaltered naphthalene. Bamberger and Lodter stated that such a product remained unaltered on further treatment with sodium and ethyl alcohol, but he had not found that to be the case. This mixture was readily separated by converting the naphthalene into the picrate, but by repeated crystallisation from alcohol the melting point was only raised to 59° C., at which point it remained constant. Bayer's patents, which he had mentioned, covered the action of alkaline-earth metals, which would no doubt give similar results, but he had only worked with sodium. The condensation products of hydrogenated amines with aldehydes had only been studied in the case of formaldehyde and α -tetrahydro- β -naphthylamine. C. Smith (Chem. Soc. Trans., 1904, 85, 732) prepared methylene-tetrahydro- β -naphthylamine, a product which on reduction was converted into methyl-tetrahydro- β -naphthylamine. The condensation products of dihydro- and tetrahydro- α -naphthylamine with aldehydes were being examined now. The benzylidene derivatives of these amines could be obtained in large, beautifully formed crystals—a further example of the amines resembling *p*- rather than *o*-xylylene. The hydrogenated naphthalene hydrocarbons were soluble in alcohol, and it appeared probable that if a study of the series of compounds, naphthalene, the isomeric dihydronaphthalenes, tetrahydro, perhydro, and decahydronaphthalene were made, as had been suggested, there would be some stage in the hydrogenation at which the compound would burn without the deposition of soot. He had not

tried chromyl chloride as a reagent for the identification of the isomeric dihydronaphthalenes. There was no real difficulty in identifying these compounds as the dibromides, provided pure specimens of these compounds were available for comparison.

PROFESSOR F. P. BEDSON IN THE CHAIR.

PECTINS IN VARIOUS PLANTS.

BY ARTHUR J. W. HORNBY, B.SC., A.I.C.

In an investigation of the substances not usually determined in the analysis of cattle foods, the pectins were found to vary greatly for different foods. Examination of fresh plants by Fellenberg's method also showed that the methyl pectate content of different parts of plants varied greatly.

Fellenberg has shown that various pectins yield 35–46% arabinose, 6–10% methyl-pentosan, 50% galactose, and 7–11½% methyl alcohol on hydrolysis with soda, and his method of estimation depends upon the scission of the methyl alcohol on treatment with dilute caustic soda solution (see J., 1917, 1190; also Chem. Zentr., 1916, i., 530, and Biochem. Zeits., 1918, 85, 118).

Fellenberg's method not only affords a method of estimating small quantities of methyl alcohol in the presence of ethyl alcohol, but gives very good comparisons of the methyl pectate content of various plants and furnishes data as to part of the hitherto undetermined constituents of food substances.

Thus, in the analysis of turnips, after the percentages of water, protein, oil, soluble carbohydrates, fibre, and ash have been determined there always remains about 2% of undetermined matter, and, as can be seen from the following tables, the pectin substances go far to make this up.

As some of the methyl compound is destroyed in the process of drying, the fresh material was used in later investigations, and the amount of dry matter determined separately at the same time. As will be seen from the tables, there is in every case much more in the epidermal tissue than in the cortex. Also, when plant substances were affected by insects or by mechanical injury to the tissues, the subsequent wound tissue contained more methyl pectate than normally; for example, when living potato was scabbed by mechanical means, such as cutting with a knife, more of these pectins were formed in the wounded tissue. Also exposure of the potato to light, as in sprouting, developed more pectin in the green epidermis and inner cortex than is found in the normal tuber.

It is highly probable that this pectin has a protective effect, especially against insect attack. Methyl alcohol seems to be a strong irritant to insects, and the ease with which methyl alcohol is split off from the pectin seems to indicate that it would be liberated by the digestive juices of the insect. This may explain the immunity of the parsnip against insect attack when compared with carrots or potatoes.

Different parts of the same root vary in pectin content; e.g., parsnip near the crown contains more than other parts of the root, in both the epidermis and cortex, just as the dry matter and sugar content also vary.

In the tables the figures given for methyl pectate in the dry matter and fresh material are average percentages for the whole, whole peel, or whole flesh, as the case may be, although the moisture in every part of the root under investigation was determined separately.

Root and part of root.	Remarks.	Variety.	No. of determinations.	Methyl pectate.		Dry matter %
				In fresh material, %	In dry matter, %	
<i>Parsnip</i>						
Peel ..	"Hollow Crown"		4	4.14	15.15	34.4

Whole ..	"Up-to-date"		4	1.18	9.08	13
<i>Garden beet</i>						
Peel ..			12	3.8	14.75	25.75
Flesh ..			12	1.25	10	12.5

	Number of determinations.	Percentage of methyl pectate in dry matter.
<i>Fruit peels—</i>		
Orange	12	25.3
Apple	12	17.3
<i>Leguminous seeds—</i>		
Bean spermoderm	1	6.34
Embryo	1	1.40
Earthnut spermoderm	1	6.56
Embryo	1	3.20
<i>Cakes—</i>		
Linseed	12	2.61
Palm kernel	12	0.27
Linseed chaff	1	2.47
Oat straw	3	0.80
Meadow hay	4	1.20
Malt	12	1.34
Bran	12	0.12
Ordinary cork	12	2.49

In conclusion, it may be suggested that a methyl compound might form an efficient spray against insect attacks, although at present the expense of such compounds seems to be prohibitive. These investigations are proceeding.

I have to thank Mr. Collins, of the Agricultural Department, Armstrong College, for his kind assistance and supervision in this work.

Communications.

PROPERTIES AFFECTING STRENGTH IN WHEATEN FLOUR.

BY F. J. MARTIN, M.A.

Strength of flour.—One of the greatest drawbacks in the study of wheaten flour has been the

multiplicity of definitions of "strength": the most recent of these, that of Humphries and Biffen (J. Agric. Sci., 1906, 1, 1), defines "strength" as the capacity of a flour to produce a large and well-piled loaf; it is certainly a statement of what the miller means by the term, and this definition is used throughout this paper. Strength, therefore, is obviously a quality or a combination of qualities, the measure of which can only be judged empirically, unless and until it is possible to give accurate and quantitative significance to the words "large and well piled." Empirical judging in the form of "Bakers' marks" is at present the only way of obtaining a final judgment as to the strength of a flour, and the object of the work recorded in the present paper was to find out whether flours of different "strengths" possessed any qualities which could be determined by chemical or physical means without a baking trial.

Effect of gluten on "strength."—A large amount of experimental work on "strength" in the past has been concerned with the amount and properties of the gluten. One of the earliest methods suggested for estimating strength consisted of washing away the starch and drying and weighing the residual gluten. Experience of this method, however, showed that the amount of gluten did not determine the baking quality, and therefore the cause of strength should be sought in the quality rather than the quantity of the gluten. Considerable advance was made by the investigations of Osborne (cf. J., 1895, 293), who showed that gluten must be regarded as consisting of two proteins, gliadin and glutenin, which could be separated by their difference in solubility in dilute alcohol, in which glutenin is insoluble. Applying this fact to the problem of strength, Fleurent (Comptes rend., 1896, 123, 755) examined a number of flours, and stated that the proportions of gliadin to glutenin in good gluten (i.e., from a strong flour) was as 3:1, and that any departure from these proportions was accompanied by a lowering in quality.

Working on similar lines, Guess (J. Amer. Chem. Soc., 1900, 263) concluded that both a high gluten content and high gliadin-glutenin ratio were associated with strength. It was found, however, by experience gained in actual baking, that these results were not sufficient to assess the "strength" of a flour, and later work by Fleurent (Comptes rend., 1901, 132, 1421), in which he determined the gliadin by a new and rapid method, showed that variations in gliadin content of different flours did not affect the "strength" to an extent appreciable for the purposes of the baker.

Effect of gas-producing capacity on "strength."—Wood (J. Agric. Sci., 1907, 2, 139) divided the factors affecting strength into two classes, viz., those affecting the size, and those affecting the shape of the loaf. He considered that the capacity of a flour for giving off gas when incubated with yeast and water was the factor which in the first instance determines the size of the loaf. Further work by Humphries and Simpson (7th Int. Cong. Appl. Chem.) suggested that it is the gas evolved in the latter stages of fermentation which is the more important factor.

Effect of mineral constituents on "strength."—Continuing his researches on "strength," Wood (J. Agric. Sci., 1907, 2, 293) drew attention to the effect of varying concentrations of acids and salts on the physical condition of the gluten, and suggested that the relation between the concentrations of acid and soluble salts in the flour is the factor on which the shape of the loaf depends. Subsequently ("Technology of Breadmaking," Jago, p. 323) Wood found that the salts having the greatest influence were water-soluble phosphates, and

that a high percentage of soluble phosphates was associated with good gluten. Hardy (Brit. Assoc. Reports, 1909) also dealt with the influence of electrolytes on the cohesive power of gluten. It may be remarked here, however, that it is doubtful whether the concentration of electrolytes in flour can affect practical baking results, as in normal breadmaking it is customary for the baker to add over 1% of salt to the flour, an amount many times in excess of the soluble mineral constituents naturally present in flour.

Effect of enzymes on "strength."—A considerable amount of work has been carried out in recent years on the amylolytic and proteolytic enzymes of flour (Baker and Hulton, J., 1908, 368; Ford and Guthrie, *ibid.*, 389). The chief points established having a bearing on the present paper are (1) that the presence of an amylolytic enzyme is necessary to provide the sugar required for yeast fermentation, and (2) that the presence of a proteolytic enzyme has distinct deleterious effect on the baking qualities of the flour.

EXPERIMENTAL.

Scope of experiments.—From the above resumé it will be seen that the following have been suggested as factors determining strength:—

- (a) The total amount of gluten.
- (b) The gliadin-glutenin ratio.
- (c) The amount of gas which can be obtained by fermentation.
- (d) The concentration of electrolytes, especially phosphates.

The present paper records the experiments carried out on all these points with a number of flours, together with observations on the gas-retaining capacity of the dough, the water-soluble proteins, and the baking marks.

In selecting flours for experimental work care was taken to avoid those which might have been treated previously by the miller with soluble diastatic, phosphoric, or ammonium compounds.

Effect of the gas-producing capacity on the strength of flour.—Previous work has shown the effect of gas-making capacity on the size of the loaf, and some attempts have been made to correlate size and gas-producing capacity. As it did not appear that size invariably corresponded to the gas produced, the following experiments were carried out. Six flours were selected and baked under laboratory conditions, the following amounts of materials being used in each case:—Flour, 750g., water 400g., salt 1.2%, yeast 1.0%. The doughs were made up and allowed to ferment for 4 hours, at the end of which time they were handled, weighed and placed in tins to prove, the proving period being 45 mins. The flours were then baked and the resulting loaves measured three hours after being removed from the oven. At the time of making up the doughs each was sampled and aliquot portions, enclosed in tubes connected with a gas-measuring apparatus, were incubated at 29° C., readings being taken to correspond to the proving period, and the total gas at 24 hrs. The results in Table I. show that neither the total gas nor the amount liberated during the proving period determines the size of the loaf:—

It appeared that five of the flours used were good gas-producers, and the sixth fairly good; it was therefore decided to select a flour with poor gas-making capacity and by the addition of diastatic reagents to increase the amount of gas produced in order to determine if this increase was reflected in the size of the loaf. A sample of North Russian flour was selected and baked under the conditions described for the previous experiment, the

same proportions of flour, water, etc., being used. The diastatic reagents added were pure diastase, and the proprietary preparations known as "Diastafor" and "G.E.₁₀." It will be seen from the figures given in Table II. that there was an increase in size in the case of each of the diastatic reagents added

From these experiments it is seen that whereas the total amount of gas does not permit a value to be assigned to the size of the resultant loaf, yet in

on the first rise eliminates any effects due to the rate of gassing.

The effect of the quantity of gluten present was first examined. A strong flour, containing over 12% gluten, was selected and diluted with calculated quantities of wheat starch so that the percentage of gluten present in six mixtures varied from 7.5% to 12.02%. The doughs were made up in the following proportions:—Flour and starch 20g., water 11g., salt 1.2%, yeast 1.0%. The doughs were then rammed down into measuring cylinders and incubated at 29° C., the gas given off during fermentation being collected over brine in another set of cylinders, and the volumes of the doughs and the amounts of gas produced were read at frequent intervals (Table III). Curves plotted to show the relation between the amounts of gas generated and the volumes of the doughs were fairly regular for the first part of the experiment, but erratic for the latter part, the irregularity coinciding with the appearance of holes in the surface of the doughs (the equivalent of over-proving in baking practice). Consideration of the doughs was therefore limited to that period preceding the appearance of the holes.

order to obtain a large loaf an adequate supply of gas must be available: a deficiency of gas can, however, be rectified by the addition of suitable diastatic preparations.

Effect of the amount of gluten present on gas-retention.—It being generally accepted that the figures relating to gas production are not sufficient to indicate the size of the loaf, the next factor considered was the capacity of a flour, when in the state of dough, to retain the gas produced.

In the following method of estimating the gas-retaining power of a flour the volumes attained by the doughs during the first rise (i.e., during the first 2 or 3 hours) was considered, since it was found by experience that the rate of gas production during this period was approximately the same in all cases. At later stages during the fermentation the rates of gas-producing vary greatly for the different flours and in some cases the amount of gas produced is not sufficient to distend the dough to its maximum size. The consideration of the volumes

Table III. shows that the rate of gassing was very even throughout the series of doughs, but that the volumes of the doughs varied considerably. It will be seen that the amount of gas retained by the various doughs, after the evolution of 45 c.c. in each case, varies with the percentage of gluten in the dough.

Variations in power of gas-retention of the gluters from different flours.—Attention has frequently been called to the variations in the physical properties of the gluters derived from different flours, and experiments were therefore made to see if there were any marked differences between the gas-retaining power of these gluters when fermented under similar conditions, the percentage of gluten in the flours being the same. A series of flours was taken, and after determining the amount of gluten present, the flours were diluted to a common gluten content of 7.0% by the addition of pure wheat starch. Doughs were then made up in the following proportions:—Flour and starch 20 g., water 10.5 g., salt 1.2%, yeast 1.0%. The doughs were rammed down into measuring cylinders and fermented at 29° C. as in the previous experiment. The amount of gas evolved and the volumes of the doughs were read at frequent intervals; the readings are given in Table IV.

The gas-retaining powers of the doughs are given in Table V., from which it will be seen that there is marked difference in the gas-retaining powers of the gluters from various sources.

Comparison of the chemical and physical properties of flour with baking properties.—A number

of factors having been suggested as having some effect on the strength of flour, it seemed possible that if an examination of the flour, embracing all these points, were made, some combination of factors might be found that would indicate the baking values of the flour. Straight grade flours from single wheats were selected for examination: these flours differed widely in baking properties and in origin, including wheats from England, Russia, India, Australia, and North America. The following determinations were made in each case:—

(1) *Total gluten*, determined by estimating the total nitrogen and multiplying by 5.7, also by washing out the gluten and drying at 100° C.

25° C., the mixture being thoroughly shaken at half-hour intervals. At the end of 3 hrs. the mixture was filtered, the filtrate evaporated to dryness in the water bath, and the residue dried at 100° C.

(7) *Water-soluble nitrogen*.—The nitrogen in the filtrate from No. 6 was estimated.

(8) *Water-soluble phosphorus*.—The phosphorus in the filtrate from No. 6 was estimated and taken as the soluble phosphorus expressed as P_2O_5 .

(9) *Acidity*.—5 g. of flour was mixed with 50 c.c. of water and the mixture immediately titrated with sodium hydroxide, phenolphthalein being used

(2) *Gas-retaining power of gluten*.—This was estimated empirically as described above, the flour being diluted with starch to a gluten content of 7%. In order to give a numerical value to this factor the gluten from No. 1 Northern Manitoban Flour (Ref. No. 7 A L) was taken as the standard, and the gas-retaining capacity of the gluten under examination is expressed as the ratio of the volume of its dough to the volume attained by the same weight of the standard under the same conditions. The ratio is, of course, a measure of the total volume attained and not of the increased volume due to gas-retention, but it has proved convenient as it is more closely related to the observations made in baking trials.

5 A	46.0	7% in each case.
6 A	49.5	
9 A	51.5	
7 A	55.0	
8 A	57.5	

(3) *Gas-retaining power of flour*, estimated by multiplying the percentage of gluten in the flour by the gas-retaining power of the gluten.

(4) *Crude gliadin*.—The flour was treated with 50% alcohol (by weight) in a Soxhlet extractor, using the minimum quantity of liquid. The extraction was allowed to proceed until no further protein was extracted. Using 1–2 g. of flour it was found that all the alcohol-soluble protein was removed in 3 hrs. The nitrogen in the extract multiplied by 5.7 is taken as “crude gliadin.”

(5) *Glutenin*.—The crude gliadin-nitrogen subtracted from the total nitrogen was taken as the glutenin-nitrogen. This figure multiplied by 5.7 gave the amount of glutenin.

(6) *Water-soluble extract*.—25 g. of flour was treated with 250 c.c. of water for 3 hrs. at 24°—

as indicator: the result was expressed as g. H_2SO_4 per 100 g. flour.

(10) *Gas-producing capacity* was measured by the method suggested by Wood (*loc. cit.*). A dough was made up of 10 g. of flour and 5 g. of water, with 1.2% of salt and 1.0% of yeast, and fermented at 29° C. for 24 hours. The amount of CO_2 produced in that period was taken as the gas-producing capacity.

(11) *Baking properties*.—The flours were baked by a short, straight dough process, the fermentation period in the troughs being four hours. Two series of trials were made; in one series nothing was added to the flour, while in the other series enough diastase was added, where required, to render the flour able to produce sufficient carbon dioxide on fermentation. Each trial consisted of baking about ten “cottage” loaves and two “tin” loaves. Bakers’ marks were awarded by Mr. A. E. Humphries, under whose direction these trials were made. The standard to which these marks refer is that of No. 1 North Manitoban flour 100 and Average English 65. Under this system of marking a good household flour has a mark of about 84.

The results of the examination of the flours are given in Table VI. Attention is called to the difference in Bakers’ marks due to the addition of diastase only.

The figures in Table VI. indicate that there is no connexion between the gas-retaining power of the gluten and either the amount of water-soluble extract or water-soluble phosphorus or acidity.

Also, there is no definite relation between either the crude gliadin or glutenin, or the ratio of these, and the gas-retaining power of the gluten.

Extraction of water-soluble protein by dilute alcohol.—The work of Chamberlain (J. Amer. Chem. Soc., 1906, 1657) demonstrated the presence of proteins other than gliadin in the alcohol-soluble extract, and experiments were accordingly carried out to see if the water-soluble proteins were also soluble in 50% alcohol.

A flour was first extracted with 50% alcohol in order to estimate what has previously been termed in this paper "crude gliadin." Another sample of the flour was extracted with water by shaking vigorously for 5 min., centrifuging, and decanting through a filter. The residue was then washed

be due to their action on the water-insoluble proteins, converting these into a soluble form. Experiments were therefore made to see if the action assigned to the proteolytic enzymes was directed to transforming the gliadin or the glutenin into water-soluble proteins during the earlier stages of their

with water by shaking for 2 min., centrifuged, and decanted through a filter and the nitrogen estimated in the mixed filtrates. The whole of the water extraction was carried out in 15 min., the flour being separated from the solution by centrifuging, so that practically no flour was in contact with the water in the filter paper. The water-extracted flour was then extracted with 50% alcohol, and the nitrogen in the extract estimated. The results (Table VII.) show that 50% alcohol dissolves a considerable proportion of the water-soluble proteins:—

TABLE VII.

Material extracted.	Solvent.	Nitrogen. %
1. Flour S.	50% alcohol.	1.00
2. Flour S.	water.	0.21
3. Residue from 2 ..	50% alcohol.	0.80

Effect of time in the estimation of the water-soluble proteins.—Difficulties experienced in estimating the amount of protein soluble in water indicated that the length of time the flour was in contact with the water had an appreciable effect on the amount found, and the following experiment was therefore made in order to ascertain the quantitative significance of the period of extraction. A sample of Sudan flour was extracted for periods varying from 15 min. to 4 hrs., and the results (Table VIII.) show that the amount of soluble protein found increases with the period of extraction. This increase is thought to be due to the action of proteolytic enzymes, the presence of which have previously been demonstrated in some flours (Ford and Guthrie, *loc. cit.*).

TABLE VIII.

Time of extraction	Soluble protein, %.
15 mins.	1.02
1 hour	1.30
2 hours	1.34
3 hours	1.40
4 hours	1.45

Source of increase of water-soluble proteins.—Amended gliadin figure.—Previous workers have noted the presence of proteolytic enzymes in flour, and the increase in soluble proteins is thought to

action. A sample of the flour used in the previous experiment was therefore extracted with water at 30° C. for 4½ hrs., and after removing the water-soluble protein the residue was extracted with 50% alcohol. The results recorded in Table IX. indicate that the water-soluble proteins have increased at the expense of the alcohol-soluble proteins:—

TABLE IX.

Material extracted.	Solvent.	Duration of extraction.	Nitrogen. %
1. Flour S.	50% alcohol.	—	1.00
2. Flour S.	water.	4½ hrs. at 30° C.	0.42
3. Residue from 2 ..	50% alcohol.	—	0.54
4. Flour S.	water.	15 minutes.	0.21
5. Residue from 4 ..	50% alcohol.	—	0.80

Since it appeared that the greater proportion of the water-soluble protein was also soluble in 50% alcohol, and that the increase in the water-soluble proteins, formed by incubating flour and water, was accompanied by a corresponding decrease in the alcohol-soluble proteins, it was decided to amend the "Crude gliadin" figure by deducting from it the amount of protein found soluble in water after a long extraction period. The result obtained was called the "Amended gliadin" figure, and in the method used for determining the water-soluble protein the extraction lasted 3 hrs.

Relation of "amended gliadin"—glutenin ratio to gas-retaining power of gluten.—The "amended gliadin" figure was estimated for the series of flours previously dealt with, and the ratio of the "amended gliadin" figure to the glutenin calculated. The results, compared with the figures obtained in the cylinder experiments for gas-retaining capacity (Table X), show that there is a fairly close agreement between the amended gliadin-glutenin ratio and the gas-retaining power of the gluten, a high ratio corresponding to a good gluten.

Comparison between "amended gliadin" figure and bakers' marks.—Since the gas-retaining capacity of a flour is correlated with the "amended gliadin"—glutenin ratio, and also with the amount of gluten present, it was thought that the "amended gliadin" figure would give a good indication of the size of the loaf. Table XI. shows that there is a close agreement between the percentage of "amended gliadin" and the bakers' marks (diastase added where required).

Combination of gas-producing and gas-retaining capacity.—Both these factors exert a great influence on the resulting loaf, and an ordinary baking trial does not indicate either the capacity of gas-production or the power of gas-retention. It is, however, a simple matter to estimate the gas-producing capacity of a flour, and where deficient to increase it by the addition of a suitable diastatic reagent; when this is done, the baking of the resulting flour demonstrates the capacity of the flour to retain the gas liberated within the dough.

The series of flours already dealt with were baked under these conditions, and the gas-retaining capacity and "amended-gliadin" figure compared with the bakers' marks (Table XII.). It will be seen that these three sets of figures are closely correlated. In the same table the figures for gas-production, the amount of diastase added in the form of "diastafor," and the calculated gas-producing capacity as the result of adding diastase are given, in order to show how the absence of gas-producing power is overcome.

SUMMARY.

1. An investigation has been made as to the relations between various properties of flour and "strength."

2. No correlation appears to exist between strength and the amounts of total soluble extract, soluble phosphorus, or acidity.

3. A strong flour must possess a *minimum gas-producing capacity* as measured by the amount of gas produced by fermentation during 24 hours. A deficiency in this respect can be rectified by the addition of an amylolytic enzyme, e.g., a diastase preparation.

4. A strong flour possesses a *high gas-retaining capacity*. This has been shown to be due to the amount and form of the proteins in the flour.

5. The water-soluble protein increases with the length of the period of extraction, probably due to proteolytic enzyme action, at the expense of the alcohol-soluble protein.

6. In estimating the gliadin present in flour it is necessary to make allowance for the water-soluble proteins, which are soluble to a great extent in dilute alcohol.

7. Flours with high gas-retaining capacities and high bakers' marks have been shown to be those in which the "amended gliadin" figure is also high.

8. For flours having a satisfactory gas-producing capacity (see 3), bakers' marks, gas-retaining capacity, and "amended gliadin" content are closely related, and it is considered that the estimation of either of the latter together with the determination of the gas-producing capacity will indicate the "strength" of the flour.

The author, in conclusion, wishes to express his indebtedness and thanks to Mr. A. E. Humphries for permission to make use of figures obtained while working at Coxes Lock Mill, Weybridge, and to Dr. A. F. Joseph for assistance in preparing this paper.

Wellcome Tropical Research Laboratories.
Khartoum, March, 1920.

THE PRESERVATION OF VULCANISED RUBBER.

BY HENRY P. STEVENS.

Some time ago I was informed that vulcanised rubber kept in a tin box over a layer of ordinary kerosene remains in a serviceable condition for a much longer period than if kept in air. I therefore determined to test the preservative effect of kerosene and other vapours. The results confirmed the claims made for kerosene vapour and also showed that water vapour has a similar or even more marked effect.

For the experiments I used various vulcanised mixings to hand, consisting of plantation crêpe or smoked sheet (90 parts) and sulphur (10 parts). I had previously investigated the effect of ageing in air on vulcanised rubber rings of this composition (J., 1916, 872; 1918, 305 T and 341 T), so that I was in a good position to note the effect of ageing under varying conditions.

Preliminary tests having shown that kerosene vapour had a marked preservative effect, experiments were made with a number of rings kept in small desiccators over kerosene in a dark cupboard. The controls were placed in an empty desiccator to protect them from laboratory fumes. The experiment was extended to include some rings placed in moist air with a layer of water instead of kerosene at the bottom of the desiccator, and other rings in dry air over calcium chloride. Rings were cut from two vulcanised rubbers, A and B; A with a coefficient of 3.02, that is to say, cured to give a

reasonably long life under ordinary conditions and likely to improve on keeping for a few months, and B with a coefficient of 4.50—that is to say, over-cured and likely to show an appreciable deterioration in a few months.

Rings from both rubbers serving as controls were also tested at the commencement of the ageing period (6½ months).

Sample.	Controls, tested 27/3/18. (1)	Aged specimens, tested 19/11/18, preserved in			
		(2) laboratory air.	(3) air saturated with moisture	(4) dry air.	(5) over kerosene.
A. Breaking strain, g. per sq. mm. Final length: original=1 ..	1450 10.69	1510 9.77	1670 9.79	1360 9.34	1670 10.30
B. Breaking strain, g. per sq. mm. Final length: original=1 ..	1740 9.51	1430 8.33	1600 8.71	180 2.79	1525 9.11

The specimens kept over kerosene were swollen and were therefore hung in air before testing. They still retained a little petroleum when tested, which probably accounts for the rather high figures for final length as compared with the remaining specimens.

The figures demonstrate the preservative action of water and kerosene vapours, both of which appear to be effective. With sample A improvement results with ageing; with sample B there is some falling off in breaking strain, but it is small. Dry air gives the lowest figures, and in sample B the rubber is perished. Laboratory air contains some moisture, and the figures are consequently intermediate between dry air and air saturated with moisture. The contrast between the supple rings aged over moist air or kerosene and the harsh feel of those aged in dry air is very striking.

The preservative effect of moisture in the air is a matter of great interest and not previously remarked on or demonstrated.* It is quite common to find rubber goods stored in a dry place, whereas a damp, cool cellar would be preferable. The results also have a bearing on physical tests made on vulcanised rubber in the East. I have already shown that temperature is an important factor in ageing (J., 1918, 281 r), and have suggested that the test rings should be kept in an incubator at the average temperature of the tropics during the period between vulcanising and testing, so as to enable tests to be made in Europe to correspond with conditions in the tropics. It now appears that the atmosphere surrounding the test pieces in the incubator should be kept moist. Similar con-

* Since the above was written I have been informed that rubber stoppers have been preserved in water for 30 years. Although the action may be the same, immersion in water is not so generally applicable to rubber goods as preservation in a moist atmosphere.

siderations apply to the so-called "accelerated ageing test," in which the specimens are heated in an oven to a temperature not exceeding 70° C. The results will differ from similar tests in a moist atmosphere or ageing tests at room temperature.

Further experiments were made in which the rings were suspended in stoppered bottles placed in an incubator at 30° C. to bring the temperature nearer that in the tropics. An attempt was made to substitute low-boiling petroleum for kerosene, as the vapour of the latter contains relatively high-boiling constituents which are difficult to remove from the rubber when once absorbed. Unfortunately, the more volatile petroleum vapour escaped from the stoppered bottle in a week or two at the elevated temperature. To remove the high-boiling constituents from the rubber the rings were soaked in low-boiling petroleum and air-dried before testing. The specimen of rubber taken was over-cured, having a coefficient of vulcanisation=4.79.

		in air saturated with moisture.	in kerosene vapour.
Breaking strain, g. per sq. mm.	1650	1330	840
Final length: original=1	9.89	8.45	9.08

In this experiment air saturated with moisture appears to have a greater preservative action than the kerosene vapour. As, however, the more volatile constituents of the kerosene vaporise and escape during the first few weeks of the treatment, the air in the later stages of the experiment will not be so fully charged with kerosene vapour as at the commencement. The kerosene-preserved rings were soft and supple although weak and partly perished. The kerosene vapours absorbed appear to counteract the harsh feel of rubber perished in the air. The soft and supple feel of kerosene-preserved rubber is not therefore to be taken as indicating that perishing has not taken place.

When vulcanised rubber ages only a small increase is shown in the coefficient, provided the rubber is not considerably over-cured.† It was of

† The present communication was written before the publication of Eaton and Day's paper entitled "Ageing experiments on vulcanised plantation rubber" (J., 1919, 339-347r). These authors have also noted the increase in combined sulphur which takes place on ageing and are apparently under the impression that they were the first to show definitely that such increase takes place. This, however, was already a well-ascertained fact (cf. Hinrichsen, Koll. Zeits., 1911, 8, 245; Speace, Koll. Zeits., 1912, 10, 290, and 1912, 11, 28; Van Rossem, Netherland Govt. Inst. Comm., Pt. 6, p. 219, as well as numerous determinations of my own, J., 1918, 305-306r and 340-342r, in the latter of which a correlation between the value of the coefficient and the amount of increase during ageing under uniform conditions is revealed). Eaton and Day also refer to the formation in one case of a volatile "sulphide." I had previously noted the formation of a volatile sulphur compound in all cases where a thoroughly perished acetone-extracted rubber was kept in a dry atmosphere (J., 1919, 192-196r) and I gave some account of its reactions and properties which are being further examined.

interest to ascertain whether this increase is influenced by the medium surrounding the specimen. As one could not be certain of removing the remains of petroleum from the specimens preserved over kerosene, all specimens were weighed both before and after acetone extraction, and the coefficient calculated on the weight of both the original and extracted rubbers. In the figures below the percentage loss on acetone extraction is also given. The vulcanised rubbers used were both appreciably over-cured, with coefficients C=5.53 and D=5.48. The rings were hung in bottles as before in an incubator at 30° C. The air in one bottle was kept dry by sticks of caustic potash.

It is probable that the deterioration in kerosene vapour resulted, as before, from the loss of the volatile constituents.

The loss on extraction of the moist air samples (3) only slightly exceeded the free sulphur, so that practically nothing but free sulphur and so-called resinous matter present in the original rubber was extracted by the acetone. On the other hand, both of the dry-air perished samples (2) lost about 10½%, which, after subtraction of the free sulphur, leaves 7–8% of vulcanised rubber extracted and dissolved out by the acetone.

In a previous paper (J., 1919, 1917) I showed that vulcanised rubber gradually becomes more soluble in benzene the more it is perished; eventually it becomes soluble in acetone also. As part of the perished vulcanised rubber specimens C and D under (2) dissolves in acetone, together with the sulphur with which it is combined, it follows that the coefficient, if calculated in the usual manner on the original weight, will be too low, and the correct figure will be a higher one, obtained by basing the calculation on the weight of the specimen after acetone extraction. This increase in the coefficient amounts to about ½% in the above examples. The following figures were obtained by analysing a number of specimens vulcanised to varying degrees, weighing the rubber both before and after acetone extraction.

Coefficient calc. on weight before acetone extraction.	Coefficient calc. on weight after acetone extraction.	Loss by acetone extraction, % by wt.	Free sulphur extracted (by difference), %.	Matter extracted other than free sulphur, %.

6.38	6.85	10.6	4.3	6.3
6.02	7.49	10.5	3.8	6.7
7.29	9.04	20.8	3.7	17.1

The figures in the last column show that newly vulcanised rubber yields about 3% of acetone extract in addition to the free sulphur, whatever the coefficient may be, but that, after perishing, the extract may attain any figure. It may be concluded that previous published figures for the combined sulphur or coefficient of rubber after ageing, including my own (J, 1918, 305–6 T and 340 T), are too low for those specimens which were perished.

From the above results, particularly the constancy of the acetone extracts after ageing, it appears that the preservative action of water or kerosene vapour is due to an actual chemical preservation of the vulcanised rubber. These agencies inhibit or retard the chemical changes, including oxidation of the rubber, which normally take place when vulcanised rubber is aged in air, as shown by increase in weight and increase in acetone extract, but they do not retard the physical changes sometimes known as “after-vulcanisation,” as shown by the tensile strength and reduction of distensibility (reduced final strength) of the rings kept in air saturated with water vapour. We may therefore distinguish two changes which normally take place when vulcanised rubber ages:—Firstly, a physical change comprising an initial increase in tensile strength (if the specimen is not appreciably over-cured), and a gradual reduction in final length.

Secondly, a chemical deterioration, consisting mainly in an oxidation with a slight loss of sulphur in a volatile form. The extent of the chemical change is conditioned (1) by the coefficient of vulcanisation, the higher the coefficient the more rapid the oxidation, (2) by the atmosphere surrounding the specimen, and (3) by the temperature. I do not propose at this stage to put forward a theory to account for the preservative action of the water vapour, as further experiments to this end are in progress.

Conclusions.

1. The life of vulcanised rubber is prolonged by storing in air saturated with moisture or petroleum vapour. Even over-cured rubber can be preserved by this means for 6 or 7 months at tropical temperatures.
2. Preserved under these conditions, the acetone extract does not increase, showing that the rubber is protected from oxidation and decomposition. Nevertheless, the physical changes characteristic of “after-vulcanisation” proceed normally.
3. In dry air the chemical change (oxidation) takes place more rapidly than in air containing moisture, and an increase in the acetone extract takes place.
4. As the oxidation of soft vulcanised rubber takes place the more rapidly the higher the coefficient, and is accompanied by an increase in the coefficient, and as vulcanised rubber, when perished, tends to become soluble in acetone, the percentage of combined sulphur or coefficient in such cases should be based on the weight of the specimen after acetone extraction.

THE ESTIMATION OF NICKEL IN STEELS BY DIRECT TITRATION.

BY EDWARD H. HALL, A.I.C., B.SC.(LOND.).

The method to be described is a modification of the well-known one of the direct titration of the tartaric (or citric) acid solution of the steel by potassium cyanide.

It has long been recognised that provided chromium be absent (see Brearley and Ibbotson) the method will give results sufficiently accurate for routine work, but cannot be used where great accuracy is required. The reason usually given for this lack of precision is the difficulty of observing to a nicety, owing to the dark colour of the solutions being titrated, the point where the cloudiness produced by the silver iodide indicator is re-formed

by the silver nitrate after being first discharged by the standard potassium cyanide solution.

According to the author's experience of the method, a further difficulty is that of neutralising the tartaric acid solution of the steel before titration. The usual method of neutralising this solution is to add dilute ammonia until the solution smells faintly ammoniacal. The danger of this procedure is that the flask in which the neutralisation is made often smells ammoniacal before the solution is neutralised, and it is necessary, before smelling, to drive ammoniacal vapours from the flask. This is rather tedious and, moreover, still leaves a doubt as to the exact excess of ammonia added. The amount of this excess has a great influence on the result. It is therefore important when titrating a batch of steels against one of known nickel content or against a standard nickel solution, that precisely the same excess be used in each case. The actual magnitude of this excess, provided it be low, does not matter.

In order to make the method precise, therefore, it will be seen that the following conditions are necessary:—

(1) That a suitable means be found for viewing the appearance and disappearance of the cloudiness produced by the silver iodide indicator.

(2) That a means be found to control exactly the excess of ammonia added before titration.

The first condition is easily satisfied by transferring the tartaric acid solution of the steel before complete neutralisation to a Nessler tube (or a measuring cylinder), which is supported over a plane mirror by any suitable means. The angle of the mirror is so adjusted that light is reflected directly up the length of the tube. By looking vertically down the tube, the slightest cloudiness is apparent, even when the solution looks perfectly bright when viewed normally. The mirror can be conveniently mounted on a swivel (a microscope illuminating mirror answers the purpose admirably), so as to be able to adjust its angle, and can then be placed in a small wooden box, having one side removed to admit the light, and a hole in the top to let the reflected light through. The contents of the Nessler tube are stirred by a plunger made of thin glass rod. The second condition is met by making use of the fact that silver chloride is soluble in ammonia, and therefore a cloudiness produced by it will be discharged as soon as free ammonia is present. The application of this fact to the present problem will be apparent by following the complete method given below.

The procedure is as follows:—0.5 g. of the sample is dissolved in a 250 c.c. conical flask in 10 c.c. of concentrated hydrochloric acid, and when solution is complete 2 c.c. of concentrated nitric acid is added and the flask replaced on the water

bath to finish the oxidation. 35 c.c. of hot distilled water is then added, the flask placed on a hot plate, and the solution boiled vigorously for two minutes to expel nitrous fumes, and 12 c.c. of a solution containing 100 g. of tartaric acid per 200 c.c. is added, followed by 8 c.c. of 0.880 ammonia. The iron solution should still be acid after adding the ammonia. The flask is now cooled and the contents transferred to the Nessler cylinder or measuring cylinder, which should hold at least 150 c.c. From a burette about 2 c.c. of the standard silver nitrate solution (2 g. per l.) is run in; this will produce a turbidity of silver chloride. From a second burette dilute ammonia (sp. gr. 0.956) is run in, at the same time thoroughly stirring with the plunger, until this turbidity disappears. The neutral point is now reached. From this point an excess of 1.0 c.c. ammonia is added and then 2 c.c. of a 2% potassium iodide solution. This restores the turbidity, which is due in this case to silver iodide, which is not soluble in ammonia. The turbidity is now discharged by running from a third burette standard potassium cyanide solution (6.7 g. KCN and 1 g. KOH per l.) in slight excess, and again formed by cautiously adding the standard silver nitrate. The volumes of potassium cyanide and of silver nitrate added (including the original 2 c.c.) are noted, and from these figures the percentage of nickel in the sample is computed.

The potassium cyanide solution is best standardised by running the solutions against a steel of known nickel content; if this be not possible, after obtaining the end point of an actual estimation as described above, a known amount of a standard nickel solution is added, and the liquid again titrated. This nickel will have been estimated under almost the same conditions as that in the sample.

Having obtained the "end point" when working with a steel, a further 4 or 5 c.c. of potassium cyanide solution is run into the cylinder and the turbidity re-formed by adding silver nitrate. The quantities of cyanide and nitrate show the relationship under the same conditions as these operating in the original estimation.

The delivery stem of burette has an extension, bent twice at right angles, fused to it below the tap. This avoids the burette being directly over the Nessler tube, which would prevent it being viewed from above.

Duplicate results agree to three significant figures. For example, with one steel basic acetate separation followed by titration showed 3.42% Ni, whilst the new direct titration method gave 3.415, 3.417, 3.419%. With another steel the result with the basic acetate separation process was 3.93%, and with the direct titration process 3.924, 3.927, and 3.922%. The method embodying the modification described is very accurate and extremely rapid.

CHEMICAL SHEET LEAD.

BY D. W. JONES.

(See J., 1920, 221—224 T.)

The author writes as follows in reply to Mr. Lancaster's communication to the discussion (*loc. cit.*, p. 224 T.):—

Mr. Lancaster questions the certainty that the additions of impurities existed in the quantities stated in the tables; and, secondly, mentions the difficulty encountered in introducing as much as 0.38% copper into a pure lead.

In reply I can state that in all cases the amounts of impurities contained in the lead were proved by careful analysis.

I am in agreement with Mr. Lancaster when he states that it is a simple matter to introduce a true equivalent of a metal of low melting point into lead, but variations arise when additions of copper are made to lead. In my experience the best results are obtained by preparing a mixture of 5% copper, 95% lead, by first melting the copper and afterwards adding the lead with constant stirring. This strong copper mixture is then added to a pure "chemical" or Pattinson lead, when a much lower temperature can be employed than in the first melting, thus obviating the liquation effect referred to by Mr. Lancaster. By this means it is possible to produce sheet lead containing 0.38% copper.

ERRATA.

Page 224 T, col. 2, lines 3—5, for "His experience . . . atmospheric corrosion," read "Lead stored in the open became severely carbonated in a short time after heavy rains, but this was not the case with lead containing perhaps 0.5% Cu."

A NEW PROCESS OF CENTRIFUGAL FILTRATION.

BY W. J. GEE.

(Abridged.)

It is possible completely to remove suspended solids from a liquid, however fine the particles, in a solid drum machine by centrifugal force exerted over a sufficient time. But in many cases the last few grains per gallon of exceptionally fine particles require so much time that the output of the apparatus is severely limited. I have myself found that some 98 to 99% of the total solids could be recovered at a very high rate of feed to the machine, but to recover the other 1 or 2% the feed had to be reduced beyond what would be a commercially prac-

ticable limit. In one case, to obtain a perfectly clear effluent, I had to cut down the feed to one-thirtieth of the rate at which 98.5% was recovered.

Consequently, in cases where the liquid is required to be completely clarified, it was necessary to evolve some method of dealing with the finer particles with an efficiency more nearly approaching that at which the larger solids are dealt with by centrifugal force. The possibility of using a filter for this purpose, using the pressure derived from centrifugal force, was obvious, but a peripheral filter would readily choke, and bring one back speedily to imperforate drum conditions. Fortunately I had some prior experience which led me to consider the possibility of an exit flow under a centrifugal head, if I may use the expression, and I found in this a complete solution of the choking difficulty. The final form of the apparatus, which combines centrifugal separation with filtration through a non-choking filter, is illustrated in the accompanying sectional diagram. The drum (26)

is secured to the base (1) by a bayonet-jointed locking-ring, the base being attached to a spindle (4) suspended from a patent ball-bearing. Rotation is imparted by the pulley (32). The bearing (34/41) is supported by a conical pedestal (67), to which is riveted a top casting of steel (66). The pulley (not shown) on the main driving shaft is fitted with a clutch of centrifugal friction type, which provides means for controlling the machine. The upper end of the drum (26) is closed by a top plate (20), which makes, during rotation, a watertight joint (31). This plate is provided with a central opening through which the machine is charged; it is also held centrally on the spindle by a distributing plate (19). Depending from the top plate (20) is the container, consisting of six vertical rods (24), with attached vanes or blades (23). These extend the whole length of the drum, being connected to the top plate (20), middle plate (22), and bottom plate (25). They serve the double purpose of dividing the drum into six longitudinal compartments, and compelling the liquid under treatment to rotate with the drum, so avoiding slip.

Each compartment is provided with a thin residuum plate (54), forming a removable lining,

curved to the radius of the drum. Upon these plates the recovered solids are deposited. When fully charged the container is lifted into the position shown in dotted lines. The recovered solids may then be removed without disturbance. A duplicate set of plates is supplied with each machine, and when the charged plates are removed the other set is inserted, and the machine put again into operation without delay. The charged plates are dealt with whilst the new charge is accumulating. Fitted to the base (1) is a perforated filter cone (12), projecting into the separator drum (26). A filter medium, cloth, paper, or other suitable substance, is wound round and secured to the outside of the filter cone by screwed wire clamps (27/28). The lifting of the container in order to remove the recovered solids is effected by a screw and bevel gear operated by cone clutches, connected to a continuously running counter-shaft, belt driven from the main power shaft. A nut carrying levers is connected by wire ropes to a ball-bearing turntable, provided with means of attachment to the top plate (20) of the container. This turntable allows the container, when lifted, to be easily rotated for access to the charge.

The new centrifugal filter has the following advantages over other filtering apparatus:—

1. The rate of filtration is constant throughout the charging period.

2. The filter, once made, is used over and over again; the removal of the recovered solids does not disturb it.

3. A very wide choice of filter material is available. Such materials as filter paper, asbestos, glass cloth, and so on can be used, as bursting of filter material is eliminated.

4. The removal of the recovered solids requires much less time than the cleaning of a filter press and the fitting of clean filter cloths.

5. The wear and tear of filter material is almost completely eliminated.

6. Materials which cannot at present be filtered at all commercially in filter presses, owing to choking, can be dealt with in the centrifugal apparatus without difficulty.

7. The apparatus lends itself to heating or cooling, so that materials may be treated at any required temperature.

8. The rotor can be readily enclosed completely for the filtration of volatile or dangerous liquids, which may be treated at any pressure or temperature. In recovering suspended solids from volatile solvents, loss of solvent and danger of fire or explosion are eliminated by using a totally enclosed machine.

9. The recovered solids are graded as to fineness of particle in a very exact manner, which is unvarying on repetition, so that standard qualities of materials are assured.

London Section.

Meeting held at Burlington House, on May 3, 1920.

MR. JULIAN L. BAKER IN THE CHAIR.

THE PREPARATION OF THIOCARBONYL TETRACHLORIDE.

BY PERCY FARADAY FRANKLAND, FREDERICK CHALLENGER, AND DOROTHY WEBSTER.

Some time ago it was found desirable to determine the most suitable methods for the preparation of thiocarbonyl tetrachloride, CSCl_4 , and thio-

phosgene, CSCl_2 , from carbon bisulphide. A thorough examination of the literature revealed the almost complete absence of reliable information concerning the yields to be expected, although both these substances have found application in the manufacture of dyestuffs, their use in this manner being protected by the German Patents 234,922, 232,791, 232,792, and 232,793 (Meister, Lucius, und Brünig).

As our experiments were intended as a preliminary to the manufacture of thiocarbonyl tetrachloride on a commercial scale, it was of first importance to determine what materials might safely be used in the construction of the chlorination vessel, as well as the effect on the reaction of traces of other substances. Our experiments were always carried out in glass vessels. A superficial examination of the chlorination of carbon bisulphide in the absence of any catalyst showed that no CSCl_4 and very little carbon tetrachloride was formed. In the presence of a very small amount of iron filings carbon tetrachloride was practically the only product, while with iodine as the only foreign substance present good yields of thiocarbonyl tetrachloride were obtained. The simultaneous presence of traces of iron filings, however, completely nullified the effect of the iodine, no CSCl_4 being formed. On the other hand, pieces of sheet lead exerted no harmful influence on the activity of the iodine.

Klason (G.P. 83,124) recommends the use of a lead-lined iron pan for the preparation of CSCl_4 , but does not explain the necessity for such an arrangement. Urbain (English Patent 13,733 of 1901) states that the addition of 0.5% of iron to the completely chlorinated mixture destroys any CSCl_4 , which is thereby converted into carbon tetrachloride and sulphur monochloride. In this connexion, Mr. F. H. Garner made several experiments which clearly showed that pure thiocarbonyl tetrachloride when kept in contact with metallic iron at the ordinary temperature is completely decomposed.

A few experiments were made in order to determine the effect of metallic tin and of "copper bronze" on the chlorination in presence of iodine. In the first case very little CSCl_4 was obtained, most of the product distilling below 80° and consisting of carbon tetrachloride. The effect of tin appears therefore to be similar to that of iron. "Copper bronze" seems to have much less effect on the activity of the iodine, a yield of CSCl_4 equal to 48% of the theoretical being obtained.

Klason (*loc. cit.*) has patented a method according to which a considerable improvement may be effected in the preparation of thiocarbonyl tetrachloride. This consists in treating carbon bisulphide in presence of iodine with six atomic proportions of chlorine instead of five, whereby the sulphur monochloride (b.p. 138°) is converted into the more volatile sulphur dichloride before the thiocarbonyl tetrachloride is attacked. The sulphur dichloride may then be removed by distillation. We have only carried out one experiment on these lines. The reaction mixture was distilled at atmospheric pressure and two main fractions obtained. The first (A) b.p. up to 80°C. , was found to contain large quantities of sulphur chlorides and practically no CS_2 , CSCl_2 , or CSCl_4 . The large fraction above 80°C. (B) contained about 26% of sulphur chlorides, judging from the loss when an aliquot part was submitted to distillation with steam.

On distillation of a further portion of B it was found that the fraction boiling above 140°C. still contained about 20% sulphur chloride. This was obviously due to decomposition of the SCl_2 during distillation into S_2Cl_2 and free chlorine and indicated the necessity for the distillation of the dichloride under diminished pressure. After removal of sulphur chloride from B the total yield of CSCl_4 was 50%.

Klason gives no details concerning the yield obtained by this method, but our results certainly confirm his statement that preferential action of the extra atom of chlorine on the sulphur monochloride occurs.

Preparation of thiocarbonyl tetrachloride on the large scale.

After several preliminary experiments with smaller quantities it was found that the method now to be described could be relied upon to give a 60% yield of CSCl_4 calculated on the weight of the carbon bisulphide taken.

To about 2 kg. of carbon bisulphide, dried over calcium chloride, is added 4 g. of iodine. Chlorine (from a cylinder), dried over calcium chloride, is introduced at such a rate that the temperature is maintained at about 20°C . and almost the whole of the gas is absorbed. It is usually desirable to cool the glass vessel containing the bisulphide in cold water, except at the commencement of the reaction, when the temperature may be allowed to rise to about 25° before cooling is begun.

When the increase in weight corresponds to the absorption of five atomic proportions of chlorine, according to the equation

the introduction of chlorine is stopped and the reaction mixture is run in a thin stream into hot water contained in a large earthenware jar, into which a rapid current of steam is blown. By this means the sulphur chloride is decomposed, while the CSCl_4 distils over. Owing to the large quantity of SO_2 , which is evolved, it is necessary to employ a series of cooling vessels in which the CSCl_4 (after passing through a water-cooled condenser) may be deposited. We have usually employed four such vessels. In the first of these (which is air-cooled) the bulk of the desired compound collects. The second is cooled in ice, and the remaining two in ice and salt.

The CSCl_4 is then once again distilled in steam, in the usual way, in order to remove any unchanged sulphur chloride. It is then dried over calcium chloride and distilled (using a Young's 12-bulb column) until the temperature reaches 140°C . Experience has shown that the product then remaining in the distillation flask is pure enough to be used directly for the preparation of thiophosgene. A further quantity of CSCl_4 can be obtained by redistilling that portion boiling below 140°C . and again rejecting what has distilled below that temperature. Further small amounts of CSCl_4 can still be recovered from this low-boiling distillate, which contains in addition carbon bisulphide, carbon tetrachloride, and some thiophosgene, the presence of which is readily detected by its odour, the red colour of its vapour and the formation of the characteristic luminous, bluish fumes in presence of atmospheric oxygen. (In this connexion see *Bull. Soc. Chim.*, 1910 (4), 7, 722.)

The formation of thiophosgene was of particular interest since the ultimate object of our experiments was the conversion of the CSCl_4 to thiophosgene by means of a suitable reducing agent. The separation of this substance (b.p. 73.5°) from the fractions boiling from 70° — 80° was, however, impossible, owing to the presence of carbon tetrachloride (b.p. 78°).

Experiments in which carbon bisulphide, in presence of a trace of iodine, was treated with only two atomic proportions of chlorine in the hope of thereby reducing the formation of CSCl_4 and of CCl_4 were unsuccessful, no relative increase in the amount of the thiophosgene fraction being observed, which, indeed, under these conditions, was extremely small. These experiments are, however,

interesting inasmuch as very little carbon tetrachloride appears to be formed.

Although thiocarbonyl tetrachloride possesses a most irritating and objectionable odour, the whole of these experiments, except the large scale chlorinations, were carried out in a crowded laboratory, with careful utilisation of fume-cupboard accommodation, without occasioning serious inconvenience. When any of the product was spilt it was found convenient to cover it with sodium hydrogen sulphite, which reacts readily with substances containing the trichloromethyl group (Rathke, *Annalen*, 1872, 161, 149; 1873, 167, 202. Albrecht, *Annalen*, 1872, 161, 129).

THE PREPARATION OF PICRYL CHLORIDE. BY NITRATION OF 1-CHLORO-2,4-DINITRO- BENZENE.

BY PERCY FARADAY FRANKLAND AND FREDERIC
HORACE GARNER.

Picryl chloride was formerly obtained by the action of phosphorus pentachloride on picric acid. It can, however, be obtained by careful nitration of chlorobenzene or dinitrochlorobenzene. Once obtained, picryl chloride serves as the basis from which a large number of trinitro compounds of benzene and hexanitro compounds of diphenyl can be prepared.

The method of preparation of picryl chloride from 1,2,4-chlorodinitrobenzene was first described in G.P. 78,309, but in this patent the use of excessive quantities of nitric acid and oleum is recommended, and very few details of the method of manufacture are given. The purpose of the present investigation was to ascertain the exact conditions under which the nitration should be carried out, avoiding if possible the use of oleum and of temperatures above 130° .

The course of the nitration was followed by analysis of the nitrating mixture at short intervals. A mixture of sulphuric acid, nitric acid, and dinitrochlorobenzene was heated in a flask loosely stoppered with a plug of glass wool. The flask was immersed in an oil-bath maintained at the desired temperature. Small quantities of the acid mixture were removed at intervals for analysis. The liquor thus obtained was analysed for total nitric and nitrous acid in a nitrometer in the usual way, and for nitrous acid by means of sodium ferrocyanide and sodium citrate solutions.

In all the experiments described in this paper sufficient sulphuric acid was present to keep all the dinitrochlorobenzene in solution, and thus only one layer was present. In consequence of the large amount of sulphuric acid used no material increase in the concentration of water took place in the course of the nitration.

Crude dinitrochlorobenzene from British Dyes, Ltd., was used. When dried it melted at 43° — 44°C . (pure dinitrochlorobenzene melts at 50°C). The acids used were fuming nitric acid of sp. gr. 1.51, containing approximately 90% HNO_3 and 1% N_2O_4 , and sulphuric acid of the desired concentration made up from ordinary concentrated sulphuric acid and fuming sulphuric acid.

Setting points of mixtures of dinitrochlorobenzene and picryl chloride.

The setting points of mixtures of dinitrochlorobenzene and picryl chloride from 100% picryl chloride to 100% dinitrochlorobenzene were investigated. The dinitrochlorobenzene and picryl chloride used were pure, having been recrystallised several times from alcohol.

The curve plotted from these figures was used in the nitrations which follow to determine the degree of nitration which had taken place. There is a eutectic point in the curve at 56% dinitrochlorobenzene 44% picryl chloride and setting point 25.0° C. (corresponding approximately to 3 mols. dinitrochlorobenzene to 2 mols. picryl chloride)

Percentage of dinitrochlorobenzene.	Percentage of picryl chloride.	Setting point.
0	100	80.6°
4.7	95.3	76.6°
9.3	90.7	72.9°
13.6	86.4	70.0°

60.5	39.5	34.0°
80.7	19.3	39.9°
89.7	10.3	43.8°
100.0	0	47.9°

Preliminary experiments had shown that, owing to the large amounts of nitrous acid produced during the nitration, it was impossible to obtain complete nitration without using a large excess of nitric acid over that theoretically required.

A series of experiments was carried out to determine the relative rates of nitration at different temperatures, using 100% sulphuric acid. From these experiments the most suitable temperature for the nitration was shown to be 100° or 110° C. as regards low production of nitrous acid compared with the rate of nitration; owing, however, to the low velocity of nitration at these temperatures, the temperature of 130° C. was chosen for carrying out the bulk of the nitrations which followed.

Further experiments carried out under such conditions that varying amounts of nitrous acid were present gave products exhibiting little difference in melting points after 12 hours at 130°; it therefore appears that nitrous acid has no great effect on the nitration.

It was also found that there is no advantage to be obtained by adding the nitric acid in stages, as regards the ultimate m.p. of the product. A greater loss of nitric and nitrous acids was observed when all the nitric acid was added at the commencement, but this was counterbalanced by the longer time required for the same degree of nitration.

To ascertain whether the production of nitrous acid had any direct relation to the amount of dinitrochlorobenzene present, three experiments (one with the nitrating liquid alone, another with the nitrating mixture and a certain amount of dinitrochlorobenzene, and a third with the same quantity of nitrating liquid and an amount of picryl chloride equal to the weight of dinitrochlorobenzene in the second) were carried out at 130° C. for periods up to 12 hours. The results indicated that by increasing the amount of dinitrochlorobenzene present in a given quantity of nitrating liquid the amount of nitrous acid produced is increased in the same proportion. This holds only up to three hours, as in the case of the longer experiments the amount of free nitric acid is diminished considerably after the initial three hours heating, and this diminution is greater the more dinitrochlorobenzene is present; therefore, since the amounts of nitric acid are greatly different, the experiments after three hours are no longer comparable. It was shown by experiments using pure dinitrochlorobenzene that the production of nitrous acid is not due to impurities present in the crude dinitrochlorobenzene used in these experiments.

In the case of picryl chloride there was a slight increase in the production of nitrous acid over the control; it was, however, much smaller than in the case of dinitrochlorobenzene. The decrease in nitric

and nitrous acids was less with picryl chloride than with the control, as would be expected. Similarly, the loss of nitric and nitrous acids by evaporation in the case of dinitrochlorobenzene would be less than that of the control.

The production of nitrous acid from nitric acid in the course of the nitration considerably diminishes the rate of nitration, since the amount of free nitric acid becomes less and less as the experiment proceeds; the diminution in nitric acid available for nitration is, in fact, more largely due to the production of nitrous acid than to its withdrawal by nitration.

Experiments on the nitration of pure dinitrochlorobenzene showed that the amount of nitrous acid formed is directly proportional to the quantity of dinitrochlorobenzene present and that nitrous acid is produced to the same extent whether crude or pure dinitrochlorobenzene is nitrated; also nitrous acid is produced with picryl chloride, but to a much smaller extent than with dinitrochlorobenzene.

Carbon dioxide produced along with the nitration.

Since, from the preceding experiments, it appeared that the nitrous acid produced along with the nitration is the result of oxidation of the dinitrochlorobenzene, the question arises as to the product of this oxidation; it is obvious that if dinitrochlorobenzene were oxidised to carbon dioxide, a larger amount of nitrous acid would be formed than if only a partial oxidation took place. It therefore seemed probable that carbon dioxide was the oxidation product, since no large amount of dinitrochlorobenzene disappeared during the nitration, and also since no substance other than picryl chloride was found in the fully nitrated product.

To settle this point a series of nitrations of dinitrochlorobenzene was carried out, and the amounts of nitrous acid and carbon dioxide formed were determined at intervals. When the results were plotted as graphs it was observed that for a short time nitrous acid was formed without any appreciable amount of carbon dioxide being evolved. After this initial lag, the production of nitrous acid was proportional to the amount of carbon dioxide given off up to about 6 hours; after this a slowly increasing amount of carbon dioxide was produced per unit amount of HNO_2 formed. This increase in the proportion of carbon dioxide to the nitrous acid may be explained as follows:—During the nitration in the latter stages a certain amount of nitrous acid is lost by evaporation, and this loss will not occur in the earlier stages; consequently the amount of nitrous acid formed at twelve or nine hours will be less than that actually found, and hence the ratio of carbon dioxide to nitrous acid is too high. Possibly another factor tending to make this ratio higher is the minute amount of substances not arrested by the apparatus. This amount will be the greater the longer the time, and, as comparatively little carbon dioxide is produced in the last three hours* as compared with the first, these will affect the later results much more than they do the former.

A similar series of experiments was carried out, using picryl chloride in place of dinitrochlorobenzene. The general results of these experiments were similar to those obtained in the case of dinitrochlorobenzene. The same decrease was observed in the amount of nitrous acid as compared with the amount of carbon dioxide evolved; the amounts of these formed in twelve hours were, however, less than one-tenth of the amounts formed in the case of dinitrochlorobenzene. There was no constancy in the ratio of the amounts of carbon dioxide

* The concentration of dinitrochlorobenzene is of course greatly diminished by this time through the formation of picryl chloride, and the latter is much less oxidisable. The concentration of HNO_2 is also much reduced.

evolved to the nitrous acid in this case that was noticed with dinitrochlorobenzene (after the initial lag in this latter).

The oxidation of dinitrochlorobenzene may be represented by the equation:

(oxygen being furnished by $2HNO_3 = 2HNO_2 + O_2$). Hence 1 g. HNO_3 expressed as HNO_2 is formed by the oxidation of 0.222 g. of dinitrochlorobenzene and gives 0.289 g. CO_2 . Actually the amount of CO_2 per unit of HNO_3 produced varied according to the length of the experiment. In one experiment 1 g. HNO_3 gave 0.241 g. CO_2 after three hours, 0.261 g. after six hours, and 0.282 g. after twelve hours. There is thus an increase in the amount of CO_2 produced per unit amount of nitric acid reduced; this may be explained as either due to the retention of some of the carbon dioxide in the liquid or to the formation of an intermediate compound which decomposed giving carbon dioxide. This would also account for the amount of carbon dioxide being less than that theoretically required.

In the case of picryl chloride a similar equation can be assumed for the production of carbon dioxide, thus:—

i.e., for 1 g. HNO_3 produced, 0.289 g. CO_2 is formed. Actually it was found that after 3 hrs. 1 g. HNO_3 gave 0.065 g. CO_2 , after 6 hrs. 0.092 g., and after 12 hrs. 0.142 g. Here a mere fraction of the amount of CO_2 theoretically required is evolved. The result is in accordance with the theory as regards the retention of the gas by the liquid; here the amount retained would presumably be about the same as in the case of dinitrochlorobenzene; but, as the total amount of carbon dioxide formed is much less in the case of picryl chloride this factor would influence the results more largely. The relative amounts of nitric acid used up in nitration and oxidation respectively were established by analyses of nitration mixtures using various proportions of dinitrochlorobenzene. In all nitration experiments where the loss of nitrous acid by evaporation was small in amount the decrease in $HNO_3 + HNO_2$ † as compared with the control was only about one-third of the corresponding increase in HNO_2 . On the assumption that this decrease is wholly due to the rate of nitration it is seen that of the nitric acid which is used up $\frac{1}{4}$ goes for nitration and $\frac{3}{4}$ for oxidation of the dinitrochlorobenzene. Correcting for the amount of nitrous and nitric acids produced on oxidation of the dinitrochlorobenzene, the ratio of the amount of nitric acid used in nitration to the amount used in oxidation is 1:1.8. By comparing equation (1.) above with the following equation:

it is seen that whereas 1 g. HNO_3 nitrates 3.21 g. dinitrochlorobenzene, 1.8 g. HNO_3 oxidises 0.469 g. Hence from 100 g. dinitrochlorobenzene 88 g. of nitrated product should be produced.

It will be shown that under the conditions given later a yield of 85% picryl chloride was obtained; the agreement is good considering that the calculation is only approximate.

Production of picryl chloride.

In the following experiments the proportion of 750 g. of 100% sulphuric acid to 100 g. of dinitro-

chlorobenzene was chosen because this is about the minimum amount (slightly over, in fact) which will dissolve the dinitrochlorobenzene; the picryl chloride formed separates out to some extent as the nitration proceeds.

Various quantities of nitric acid were added to these amounts of acid and dinitrochlorobenzene, and after 3, 6, 9, and 12 hrs. heating to 130° C. portions of the nitrating liquid were poured into excess of water, when the dinitrochlorobenzene and picryl chloride separated out either as liquid or solid; in the latter case the mixture of water and solid was warmed until the solid melted, when the supernatant water was poured off. The oil thus obtained was washed with hot water and a wet setting point determined. Picryl chloride washed with water in this way gave a wet setting point of 76° C. (dry setting point 80°–81°). A nitrated product with wet setting point of 72° C. was regarded as satisfactory.

These experiments established the following facts: Using 100% sulphuric acid, there is no advantage to be obtained by increasing the proportion of nitric acid beyond 125 g. of 90% acid and nitrating for 12 hrs. Other series of experiments showed that no advantage is obtained by adding the nitric acid in stages rather than the same quantity initially, or by subjecting the nitrating mixture to a lower temperature (100° C.) previous to the use of a temperature of 130° C. Using 96% sulphuric acid, a satisfactory product is obtained after 12 hrs. heating to 130° C. from a mixture of 175 g. of 90% nitric acid, 1500 g. of 96% sulphuric acid, and 100 g. of dinitrochlorobenzene. As before, no advantage was obtained by preliminary heating or the addition of nitric acids in stages. This large excess of sulphuric acid was found to be necessary, as when only 1000 g. was used a product of wet setting point 60° was obtained after 12 hrs. heating at 130°.

It was also found possible to nitrate dinitrochlorobenzene, using 94% sulphuric acid, but even with very large quantities of sulphuric acid and relatively large amounts of nitric acid the nitration was not complete in 12 hrs. at 130°. In one experiment a product of setting point 63° was obtained with 100 g. dinitrochlorobenzene, 3000 g. 94% sulphuric acid, and 200 g. 90% nitric acid.

If the nitration were carried out at a temperature of 140°–150° C. a saving in nitric acid and time could be effected on the results recorded above. Experiments were carried out by heating for three hours at 130°, raising the temperature to 140° in half an hour, then raising the temperature to 150° over a period of three hours, and finally heating to 145°–150° for a further period of three hours. Using 100 g. of dinitrochlorobenzene, 750 g. of 100% sulphuric acid, and 100 g. of 90% nitric acid, a product equal to that obtained in the former experiments with 125 g. nitric acid to the same quantities of acid and dinitrochlorobenzene was obtained in 9½ hrs. instead of 12 hrs.

From the above experiments the following proportions of acid and dinitrochlorobenzene are suggested as the most suitable for employment to produce good nitration after heating to 130° C. for 12 hrs.

Using 100% sulphuric acid, dinitrochlorobenzene, 100 g.; sulphuric acid (100%), 750 g.; nitric acid (90%), 125 g. (35 g. 90% HNO_3 is theoretically required for complete nitration).

The wet setting points of the product were as follows: After 3 hrs., 52° C.; 6 hrs., 63°; 9 hrs., 67°; 11 hrs., 69.5°; 12 hrs., 71°.

The yield of picryl chloride was 85%, m.p. 76° C., dry setting pt. 74°–75° C.

Using 96% sulphuric acid, dinitrochlorobenzene 100 g.; sulphuric acid (96%), 1500 g.; nitric acid (90%), 175 g. Wet setting points: After 3 hrs., 48°; 6 hrs., 61°; 9 hrs., 68.5°; 12 hrs., 72° C.

* A small amount of CO is produced, but this does not invalidate these conclusions.

† The nitrogen peroxide derived from the dinitrochlorobenzene is assumed to be dissolved in the nitrating mixture and therefore estimated at the same time as that derived from the nitric acid by oxidation of the dinitrochlorobenzene. The complete equation should therefore be:

(2.) $4C_6H_3(NO_2)_2Cl + 50HNO_3 = 24CO_2 + 2H_2O + 2Cl_2 + 58HNO_2$.
† This HNO_2 includes that formed from the NO_2 groups in the dinitrochlorobenzene suffering oxidation.

The yield of pieryl chloride was 85%, m.p. 77° C., dry setting pt. 75°–76° C.

The yield and quality of the product obtained are thus practically identical, irrespectively of whether 100% or 96% sulphuric acid is employed under the conditions indicated above.

Analyses of the products showed that with 100% sulphuric acid the loss in nitric and nitrous acids (expressed as HNO_3) was 9.6 g. per 100 c.c.; the loss in nitric and nitrous acids required for complete nitration 5.9 g per 100 c.c.; and the amount of nitrous acid formed 11.2 g. per 100 c.c. With 96% sulphuric acid the corresponding figures were 4.4 g., 3.2 g., and 7.8 g. per 100 c.c. respectively. Thus, with 100% acid 3.7 g. of nitrous acid, expressed as nitric acid, is lost by evaporation, and with 96% acid 1.2 g.; this difference is due no doubt to the greater concentration of the nitric acid when 100% sulphuric acid is used.

NOTE ON THE DETERMINATION OF TAR ACIDS IN DRAINAGE FROM TARRED ROADS.

BY J. J. FOX, D.SC., F.I.C., AND A. J. H. GAUGE, F.I.C.

As a result of experiments carried out by Mr. A. J. Mason-Jones, biologist to the Joint Fisheries Committee (Tar Pollution) of the Ministries of Transport and Agriculture, it is now known that water which has been polluted by tar and in which the amount of tar acids is as little as 1 part per 100,000 is fatal to fish life. It is therefore important to possess a ready means of detecting and estimating such minute quantities of tar acids. The method described in this note depends upon the formation of the azo-dyes obtained when sulphanilic acid is diazotised and poured into water containing tar acids after it has been rendered alkaline. The depth of colour produced is matched in a Nessler tube by the colour obtained under similar conditions with a mixture of the three cresols in the proportions specified below. The tar acids in the washings from tarred roads will not as a rule include much phenol, but consist of cresols and higher phenols. The mixture of cresols used by us has been found to be generally available as regards shade of dye produced, but occasionally the matching becomes a little troublesome on account of the red shade produced by the higher phenols.

The solutions required are (1) recrystallised colourless sulphanilic acid, 1.91 g. in 250 c.c. water, (2) pure sodium nitrite, 0.85 g. in 250 c.c., (3) sulphuric acid, 1 part of strong acid (sp. gr. 1.84) to 3 parts of water, (4) 8% sodium hydroxide solution, (5) standard cresol solution containing 1 g. mixed cresols per litre. The mixture of cresols for (5) consists of 35% *o*-cresol, 40% *m*-cresol, and 25% *p*-cresol.

The diazotised sulphanilic acid solution is prepared about 5 minutes before use, by mixing 5 volumes of sulphanilic acid solution with 1 volume of the sulphuric acid, adding 5 volumes of sodium nitrite solution, and cooling in a stream of cold water.

The cresol solution used for comparing the colour is a dilute solution prepared by mixing 5 c.c. of the strong solution (5) with 95 c.c. of distilled water, i.e., 1 c.c. of the dilute solution = 0.00005 g. cresol. Weak solutions of cresols are liable to change, and the standard dilute solution should therefore be prepared just before use. The strong solution (5) is stable if kept in a cool, dark place.

To make the test, 100 c.c. (or less of a strong tar extract) of the clear water or washings is placed in a Nessler cylinder and 5 c.c. of the sodium hydroxide solution added, followed by 10 c.c. of the diazotised sulphanilic acid. On stirring, an orange-coloured dye is formed when tar acids are present. The depth of colour is matched by adding to a similar quantity of distilled water in a second Nessler cylinder 2 c.c. of the dilute standard cresol solution, 5 c.c. of sodium hydroxide solution, and 10 c.c. of the diazotised sulphanilic acid solution. This is the trial assay, and determines the amount of cresol solution to be used to obtain an exact matching of the depth of colour due to tar acids in the water under test. The best results are obtained when 1 to 2 c.c. of the diluted standard cresol solution is required to obtain equal depths of colour. This can be secured as usual in this class of work by taking smaller or larger quantities of the sample under examination. The amount of tar acid is calculated from the quantity of cresol solution required to produce equal tints.

When the washings are coloured or opalescent the tar acids can be obtained by steam distillation, taking 250 to 500 c.c. of the water and testing successive portions of the distillate. This procedure is also advantageous when traces of tar acids are suspected, as it affords a means of concentration.

We have found that very dilute solutions of various tar products, *e.g.*, certain tar acids and tar bases and naphthalene, in non-sterile water rapidly undergo biological change. For this reason the examination of samples of water for tar acids must be carried out at the earliest possible moment after collection. A delay of 48 hours may result in the oxidation of a considerable proportion of the tar acids.

From Mr. Mason-Jones' results the presence of more than 1 part of tar acids per 100,000 in effluents or road washings must be regarded with suspicion where fish life is concerned.

The test for tar acids outlined above is very delicate, much less than 1 part per million being detectable. By this means phenols in minute quantities have been found to be very widely distributed. A fuller account of this will be given on a future occasion, together with a statement of the alteration undergone by dilute solutions of phenols and tar bases under the action of bacteria.

RECESSED PLATE AND PLATE AND FRAME FILTER-PRESSES: THEIR CONSTRUCTION AND USE.

BY EUSTACE A. ALLIOTT, B.SC. (ENG.), A.M.I.MECH.E.

Although much has been said and written about the filter-press, little has been mentioned concerning working conditions and performances. The object of the present paper is to make clear the construction and meaning of the numerous variations of type for those who have not had time to give special study to the matter, and an endeavour will be made to give helpful data and suggestions as to the use of this type of plant. In order that the various particulars may be as up-to-date as possible, a special effort has been made to obtain recent data from users which will represent their normal works practice. The figures given, therefore, are not test figures taken on a small scale, but may be assumed to apply to every-day large-scale operations. It should be understood, however, that the same material may vary widely in its filtering qualities, these variations being sometimes due to almost imperceptible variations in manufacturing processes, and in considering any particular problem due weight must be given to this point.

It is proposed to deal with the subject in the following order:—

- (1) Construction of the simple or "non-washing" filter press.
- (2) Choice and care of the filter cloth.
- (3) Theoretical and practical considerations concerning pressure, viscosity, rate of flow, cake thickness, size and shape of suspended particles, etc.
- (4) Methods of feeding the press.
- (5) Washing in the filter press, with details of construction, theoretical and practical considerations and results.
- (6) Air drying, steaming, hot and cold presses, etc.
- (7) Labour in discharging.

Owing to the familiarity of the filter-press it does not usually receive the attention it deserves, which would doubtless be accorded to it if it were a new piece of apparatus, or if the simplicity of its operation were less obvious. Nevertheless, even with such an apparently simple piece of plant, the application of a little intelligence and understanding will bring increased satisfaction, both in the choice of the press itself and in working it with minimum labour costs, maximum output, and best extraction of soluble matter from the cake.

Construction of the filter-press.

A filter-press may be described as a frame in which a number of loose slabs of filter surface may be clamped to form a series of hollow chambers capable of withstanding internal pressure. The filter surface is ribbed or grooved and covered with cloth. This arrangement gives a maximum of area in a minimum of space, and is capable of modification to meet the varying conditions called for by different grades of material, both as regards thickness of cake, suitable pressure, varying filter media and arrangements for washing and steaming the cake when formed. A large variety of constructional materials can be used, and the whole plant

is of high reliability and free from tendency to break down.

Two forms of press are in general use, namely, the recessed plate type, and the plate and frame type. These are often referred to as chamber presses and frame presses respectively. In the former type (fig. 1) the rims are raised, so that when two plates are brought together edge to edge a hollow chamber is formed between them. The feed passage is taken through the body of the plate, while the filter cloths are laid over each side of the plate, forming a pressure-tight joint at the rims when clamped up, and having holes for the feed passage, which are sewn together or clipped to make a joint at the corresponding hole in the plate. This type of press has the merit of being the least expensive and requiring less labour. It is very suitable for thin cakes, owing to the free communication of the feed passage with the chambers. The usual cake thicknesses are 1 in. on the smaller sizes, 1½ in. on the intermediate and large, and up to 2 in. on the largest plates. It is not generally desirable to use recessed plates for thicker cakes than these on account of the strain on the cloth imposed by the raised rim.

The liquor enters the chamber under pressure, the solid portions being retained by the cloth, while the fluid portions pass through and drain behind the cloths through the grooves or corrugations to the exit ports. They pass finally into the filtrate trough by simple spouts if rough filtration only is in question, but more usually taps are fitted by means of which any one chamber can be isolated if the filtrate from it is muddy, due to faulty cloth. Taps are also needed for certain arrangements of washing presses. Where a liquor must not come in contact with air, or it is desired to raise it to a higher level direct from the press, it can be taken away by an enclosed outlet passage.

Recessed plates usually have a central feed, and for most purposes this is as suitable as any. It is sometimes preferred in the top corner in cases where the cake is apt to be slimy round the feed passage. By this arrangement the moist portion of the cake is readily isolated from the bulk, which is firmer and drier. Putting the passage in a corner in this manner, however, is apt to cause more strain on the cloth in a recessed type press. Bottom feed is useful if a solid cake is not to be formed, as the liquid contents of the cells can be run out before opening the press, but where the solids have a strong tendency to settle it may become choked, especially if the flow is slow.

When heavy suspensions are being dealt with, top feed is therefore valuable. In cases of this kind two feed passages are sometimes arranged at different heights so as to get the maximum consolidation of cake. It should be realised that the path of each particle is determined by definite stream lines, in conjunction with its own tendency to sink or float. Thus, with bottom feed, no large heavy particles may reach the top of the plates, unless the stream line flow is strong. There is no agitation worth speaking of in the press itself, as the small amount which may occur near each inlet port is quite powerless to cause redistribution if selective settling has been allowed to occur.

The plate and frame type of press (fig. 2) is suitable where very thick cakes are to be formed, as in this case the plates themselves are flat, and the chamber is formed by hollow frames being placed between them. This type of press is also suitable for materials which tend to rot the cloths, as the latter lie quite flat on the plate; it is a necessity if filter paper is to be employed. It must be used where very thick cakes are essential, but is not suitable for thin ones or materials of a lumpy or uneven nature, as the feed ports are generally taken in through the rim of the frames, and are

thus restricted in area. On a small press, say 25½ in. square, frames as thin as ¼ in. can be used if the feed is of a more or less liquid nature throughout the operation; ½ in. or 1 in. frames are usually quite thin enough, and where chambers exceed 36 in. square it is preferable that these should be thicker if possible. For this reason it is sometimes desirable when handling very free filtering materials, having a tendency to deposit a very hard, thick cake, to use an internal feed. Passages arranged externally to the cake are highly satisfactory for less freely filtering substances, as they isolate the moist unfiltered liquor from the drier cake.

Further, the feed holes in the cloths are clipped automatically by the joint surface of the plates and frames, and so need no sewing or special clips. The usual position for the passage is at the top centre of the press, which allows little opportunity for displacement of the feed holes in the cloths either by accidents or shrinkage. Another position in general use is in the side of the press at a little above or somewhat below the centre. Such passage is not so liable to get blocked by settlement as one in the bottom of the press, and is in a favourable position for consolidating the cake.

Enlarged sectional elevation.

passages or taps for this purpose, but except for washing presses it is rarely that these are necessary.

Press plates are usually made in cast iron for neutral or alkaline materials, or in wood for acid liquors, or for dealing with such materials as colours, which might be spoilt by contact with

Fig. 1.

Cast-iron recessed plates. Types of feed inlets and filtrate outlets.

For varnishes and gummy liquors which flow with difficulty these presses are sometimes made with four passages, one at each corner of the chamber; one of the lower passages serves as feed inlet and drain while the other three act as filtrate outlets, being joined together at the head of the press. By this arrangement the liquor has a minimum distance to travel through the grooved surface to get to the outlet passage. Further, the upper passages ensure a free escape of the air from the chamber, whereas it might otherwise have difficulty in passing through the joints when these are under heavy pressure and the cloths heavily gummed up. Sometimes presses are provided with special air

iron. They can, however, be made in bronze or aluminium, or may be covered with hard lead or vulcanite. In the latter case the vulcanite is usually supported by thin steel sheets and the joint surfaces are made of softer rubber. Such a press will deal with strong hydrochloric acid.

Wood plates have been made of a variety of materials, but on the whole the coniferous woods are the best, as these have the greatest uniformity of structure, suffer the least disturbance from medullary or transverse rays, and have less sapwood and small shrinkage. For strength, cheapness, and service generally good pitch pine is difficult to equal. Presses of this material have been

reported as withstanding very satisfactorily 8% hydrochloric and 30% sulphuric acid. The author has reports where even 10% or stronger hydrochloric acid is being used, but it is preferable not to go above 4% if at all possible. Timber has to be carefully selected for such work. After the best quality wood has been bought some 20% or 30% has usually to be rejected on first inspection, with further rejections after it has been worked up. Oak makes good press plates, and is especially good for withstanding acetic acid, while teak is sometimes reported as being more resistant to acids than pitch pine, though it is more expensive. Beech, maple, or sycamore are used as substitutes, but the previously mentioned woods are preferable. Cypress is also used, more especially in the United States. Very much depends on the quality of the wood, straightness of grain, freedom from knots and shakes, and specially freedom from sap on the filter surface. Impregnation is of doubtful value for increasing resistance to acids. Of preservative mediums paraffin wax (or coresin) is perhaps the best. It is of importance to keep wood presses

must be adequately supported with a minimum amount of dead space, though, providing the channels are free, the percentage of dead space within reasonable limits seems to make no appreciable difference in practice. Finally, smoothness and absence of sharp corners is a factor of no little importance. Covering the surface with perforated plates is only to be recommended in special cases where the adequate supporting of the cloth has to take precedence over every other consideration. Coarse-mesh gauze makes a good support. But any covering adds to the work of keeping the filter surface clean. For very viscous liquors the supporting of the cloth may have to give way to the necessity for providing very free flow at the back of the cloth, with consequent wider gaps between the supports.

In large presses, say over 36 in. square, where very high pressure or uneven filling of the chambers may be encountered, it is necessary to provide the surfaces of the plates with bosses to act as additional supports. Such bosses may be cast upon the face of the plates in the first instance, though

Fig. 2.

Flush plates and frames.

closed and moist when out of service. They should be sluiced down before dead periods and kept filled with water. Shrinking is thus avoided, and there is no opportunity for weak liquors left on the plate surfaces to concentrate by evaporation and attack them. Further, in starting up a new press the stay rods should not be too tightly screwed up but a little allowance made for the necessary expansion of the wood when first moistened. These rods can gradually be tightened up after a little use, but should not be allowed to cut into the wood.

There are various types of filter surface, ranging from very fine straight grooves to comparatively coarse pyramids or lozenges. The first and most important point is that the channels should be sufficiently deep and narrow not to be closed by the sag of the cloth. In the second place the cloth

in some cases it is preferred to add specially made bosses screwed on to the face. The great essential is that the height shall be accurate and the business surface carefully rounded off. Further, the slope must be gentle to avoid injuring the cloths. Unless absolutely necessary, such bosses are preferably dispensed with.

The design of handles requires more care than is often given. There should be ample room to get the hand in easily without any trapping or fouling. In the case of heavy plates rollers are usually fitted, and in some cases a special carriage is even arranged on which the plates can be run along the press. Some users prefer the handles to be kept very low (*cf.* fig. 40), as they state that the plates are then drawn back more evenly, and there is less tendency to tilt, and cut the cloth between the edge

of one plate and the face of another. It is doubtful, however, whether there is any real difference in actual practice, as the ordinary type of handles are very convenient to grip.

For feeding the press and for washing purposes cocks are better than the ordinary type of valve. A useful valve, however, has the screw entirely clear of the stuffing-box, and the valve itself is carried through the stuffing-box so that nothing can get at the back of it to jam. Occasionally presses are fitted with a rail running right along one side, a little below the bottom of the plates. This and the gutter serve as supports for draining trays which catch any drip, especially in the case of old wood presses. All the liquor then runs to the trough, and the floor is kept clean.

A "dead" plate, or "cutting-off plate," is a desirable fitting if batches of varying size are to be dealt with, some of which may be insufficient to fill the whole press. Such a plate has one working face only, and is sufficiently strong to withstand the unbalanced end pressure. It can be placed anywhere in the press, permitting a few chambers to be used while the rest are isolated. In default of this sufficient space may be made for the tailings of a batch by emptying a few chambers at the feed end only, leaving the remaining cakes to be removed when these have been filled again.

Fig. 3.

The question of side rods has had some attention from all makers, but it is difficult to say where the greatest advantage lies. Flat rods may be used on somewhat longer presses without support, but the plates slide more readily on the round bars, and these can be conveniently trussed in some types of press. It is important that sufficient space be left between bars and plates to give convenient room for the edges of the cloths. The plates are kept in position by distance pieces, though in the case of flat bars the handles on one side are sometimes provided with a notch for this purpose. This, however, is liable to jam if the plates are not moved back perfectly evenly.

After the plates themselves, perhaps the most conspicuous feature is the closing gear. There are

a great variety of designs, both hand and power operated, but on the whole the simplest types are preferable so long as they will give the required pressure.

The usual type of gear for small presses is the centre-screw pattern (fig. 3). This is in use for wood presses up to 36 in. or more in size, working at pressures up to 30 or 40 lb., but is preferably limited to the 25½ in. size and under. Such a gear will readily close an ordinary 25½ in. cast-iron press against 100 lb. pressure. A swinging distance piece on the head enables the latter to be drawn back after the tightening screw has been released by a couple of turns. It is sometimes arranged to run on wheels, and in the case of larger presses these are often on a common axle, fitted with a handle to give quick movement. The centre of the head is also recessed so that it can be pushed right up over the tightening screw and further play obtained. In some forms, instead of having a distance piece, the end standard is fitted with a pivot which carries the screw, so that as soon as the latter is released it can be swung up right out of the way. A common means of tightening is by a bar inserted into holes on the spindle head, a method which gives a very sure grip. Ratchet devices are, however, in common use. In a somewhat special variant of this form the screw is stationary, and a nut which revolves on it transmits the pressure through levers to half a dozen arms or rods which bear on the press head. These arms can be released and shot right back when it is desired to empty the press.

Fig. 4.

Another gear suitable for larger presses consists of a rack, fixed to the loose head, engaging a pinion on the end standard (fig. 4). By this means the head is rapidly moved backwards and forwards, while the side rods are screwed and carry wheel nuts which are tightened by levers against swinging distance pieces. Such a device will adequately close a 38 in. cast-iron press against 100 lb. per square inch or even more. It is necessary to attach the rack to the loose head by a joint, as it is found that there is slightly more accumulation of dirt at

Fig. 5.

38 in. plate and frame filter press. Spur wheel and pinion closing; and trussed side rods.

the bottom edges of the plates, and this causes the head to tilt.

Another form which is often employed is the spur wheel and pinion gear (fig. 5). This is generally similar to the centre-screw type, but the screw is driven by a large spur wheel engaging with a pinion, giving an additional multiplication of from four to eight times according to the size of the press. The pinion is fitted with a large hand-wheel for rapid manipulation, and final tightening is accomplished by levers. Sometimes both spur wheel and pinion are fitted with elaborate devices for slow and quick movement, but according to the author's observation the simpler arrangements are better, as the more elaborate are apt to consume time without giving any better closing. Such a spur wheel and pinion device permits the use of trussed side bars in the case of a long press. This arrangement obviates the necessity for supporting pillars, which may interfere somewhat with the removal of the cake from under the press. Such a gear is suitable for most duties on either wood or iron presses, but a more powerful one is the toggle

Fig. 6.

lever pattern (fig. 6). This is suitable for large wood presses up to about 48 in. The arrangement of the loose head is like the rack and pinion closing gear except that the pinion has its own spindle and hand wheel for ease in operation. The side rods, however, are not fixed to the heads but are attached to the short arms of a pair of levers which have a hinged connection to the fast head with a screw and hand wheel, by means of which their long extremities are drawn together, a very large mechanical advantage being thus obtained. The merit of the device is the ease by which one man can put on the final tightening pressure simply

Fig. 7.

by operating the hand wheel without the use of levers. The arrangement of the gear is such that perfectly even pressures are applied to both sides of the press.

Yet another form of hand-closing gear utilizes a small hydraulic pump mounted on the loose head (fig. 7). This is suitable for very high pressures or large presses. It is somewhat costly, and takes longer to operate, but puts on a perfectly definite amount of pressure, which can be regulated exactly by the gauge. In the instance illustrated the head is moved up and down by a centre screw and large hand wheel, the hydraulic ram being housed in the centre of the loose head and engaging the end of the screw. The ram carries a lock nut, which is screwed up when the pressure has been put on, preventing the press blowing or leaking when the pump pressure drops. Pneumatic closing (fig. 8) saves labour, in so far that the head can be drawn back simply by manipulating a valve, and by the

Fig. 8.

same means may be pushed back again, carrying all the empty plates with it. This is a very valuable feature in large installations having simple recessed plates in which the cloths and passages require no attention during the replacing of the empty plates. Large numbers are in use for sewage sludge. It should be remembered, however, that the actual pressure is not put on by the ram but by the wheel nuts on the side rods.

Fig. 9.

The hydraulic closing gear shown in fig. 9 has an additional advantage in that the final tightening is done mechanically, the only handwork being the operation of the locking device in case the water pressure drops. In the instance shown this

locking gear is very similar to the previous tightening gear, except that only hand pressure has to be put on the lock nuts. The loose head may be drawn back either by a special hydraulic cylinder or by weights. Where the space is small, or it is not possible to cut through the floor to accommodate the chains carrying the weights, special devices can be arranged on the top of the end standard so that the weights are kept above the floor.

division and muddy to another. Separate run-off valves may be also provided for washings. In the case of washing presses it is usual to make the trough larger and provide a plug or cock, so that it can be used as a measuring tank for the wash water.

Where presses are installed on an upper floor, discharging to the lower one, steel shoots are fitted to the fast and loose heads. If volatile liquors or those liable to give out dangerous vapours are

Fig. 11.

Plates with inserted cloths.

Cake trays are often provided to go under the press, thus saving labour in this direction. At times the whole press is arranged to stand in a special trough which completely surrounds it, and serves to isolate the cake from the rest of the floor.

The filtrate trough is sometimes arranged with a longitudinal division plate. The taps are then fitted with rubber extensions or swivel nose-pieces, by means of which clear filtrate can be run to one

being dealt with the press can be fitted with a base on to which a cover fits, the joint being made by means of a water seal or clamps (fig. 10). In this case the press is arranged with a continuous outlet passage, and the feed and any other passages are controlled by external valves.

For strong caustic liquors, which cause ordinary cotton cloths to perish rapidly, or for delicate cloths, the plates can be arranged so that the cloths

do not pass over the joints, but the latter are made by rubber or other rings let into grooves all round each rim in alternate plates (fig. 11). All the plates are then provided with a recess all round the inner side of the rim, into which the edge of the cloth is laid and made fast by a packing ring being caulked in. Alternatively the cloth may be secured by being clipped in by a joint plate which is held down by screws. Further, in such instances a perforated plate is laid over the usual corrugations, thus still more reducing the strain on the cloth, which has then a perfectly flat surface on which to rest. This arrangement effectively lengthens the life of the cloths, as the greatest wear usually takes place at the nip of the plates, and, further, if the cloth is kept well supported at every point, so that a spud cannot readily be pushed through it when the cake is being cleaned off, it may readily last, even when apparently quite rotten. A perforated plate or grid is sometimes laid over the top of the cloth. This protects it from the spud, and prevents a rotten cloth from being torn away by the weight of adhering cake. It will be realised that recessed presses of this type cannot be constructed to make thin cakes, but are suitable for thick ones from, say, $1\frac{1}{2}$ in. upwards.

Where quantities of non-viscous liquor containing very small amounts of very fine matter in suspension are to be filtered special presses are in use. The plates are not provided with a filtering surface of the usual type, but are filled with cakes of finely divided cotton pulp or other suitable material. Such a press would filter many liquors at the rate of about 4 galls. per sq. ft. per hour, and when it became clogged the pulp would be knocked out of the chambers, washed in a special washing machine, and then pressed firmly into position again by means of a special hydraulic or screw press. A usual method is to prepare the pulp cakes during the filtration period and then lay or press them in position in the specially designed plates at the end of the run, when the old pulp has been knocked out for washing.

Choice and Care of the Filter Cloth.

In recessed plate presses double cloths (fig. 12) are often used. These cloths are stitched together at the edges of the feed opening, and one cloth is passed through the feed-hole in the plate, both halves being then spread over the filter surface and

Fig. 12.

fastened at the top by clips or pins, or they may be stitched. In such cases the top of the plate carries a projection or fin for convenience in fastening the cloth. This method of fixing is suitable for most purposes, and is strongly recommended where cloths are thin or have often to be taken off and washed. For certainty in obtaining clear filtrates with fine precipitates there is nothing to equal cloths with sewn openings.

Another way of clothing the press is to take a strip of cloth, long enough to cover both sides of the plate, with two holes cut in it corresponding to the feed passage. This is hung over the top of the plate, and the joint round the feed passage is

made by clips. A very usual form of clip, the "bayonet" pattern (fig. 13), is in halves, one of which is provided with inclined projections, which engage with lugs on the other one, so that on giving a slight rotation the two halves are pressed firmly on to the cloth, making the joint. This form is the quickest to apply, but the screw pattern (fig. 14) is to be preferred as the most secure. It

Fig. 13.

is however, rather more costly. Such clips save a good deal of time and expense in stitching round the feed opening, and are useful where the cloths have to stay in the press till they are worn out. They are, nevertheless, apt to be misused. For instance, where cloths have to be taken frequently from the press for washing purposes it will be found that the double cloths previously described are much more quickly removed and replaced. In one case of a 38-in. recessed plate press having 26 chambers, using thin cloths, it was found that the use of cloth clips made a difference of three-quarters of an hour in stripping and re-clothing as between the use of double cloths with sewn centres and "bayonet" clips. Then again with thin cloths it is sometimes difficult to get clips to make a secure joint.

Fig. 14.

In frame presses cloths of double length may be hung over the plate without any special attachment or stitching, but it is best to sew them on if there are many passages in the plate rim and the cloth is to remain for some time.

Still another method is to use single cloths, caught by clips or pins at the top of the plate. The cloth top is sometimes eyeletted and engages with hooks of adjustable height. This permits ease in fixing when replacements are frequent, but sewing is the best if well done.

Fig. 15 shows a comparatively coarse precipitate of calcium sulphate (magnified 18 diameters), while fig. 16 shows to the same scale a tightly woven 18-oz. twill cloth, with no spaces between the threads, such as is used for filtering substances of a fine uniform nature, which would not be perceptible except at a much higher magnification. Such a tightly woven cloth is a necessity in some cases, say for many dyestuffs, but would be quite unnecessary for such a precipitate as calcium tartrate (fig. 17), in which the crystals range from comparatively large, say 0.1 mm. side, to very small. An open jute cloth (fig. 18) served very well for this

purpose, though even after careful shrinking many holes of 0.25 mm. side are apparent. In such a case the first fine particles pass through the cloth, while a layer of the coarser ones is rapidly built up on it, the spaces between them being so fine that even the smallest are caught. The first runnings are muddy, but soon brighten, and can be readily returned to the press, while the cloths retain their free-flowing qualities for longer than if an attempt had been made to get clear liquor at the start. The spaces between the threads in the shrunk cloth may be larger than any of the particles, but apparently the latter tend to jam, and are assisted in this by stray fibres from the threads.

Fig. 15.
Sulphate of lime ($\times 18$).

Fig. 16.
Twill cloth ($\times 18$).

In dealing with caustic soda, about 5% free alkali is as much as a cotton cloth will stand to give a reasonable life in ordinary types of press. Somewhat stronger liquors may be filtered if the cloth is treated with heavy naphtha or green oil, especially if care is taken not to allow the caustic liquor to dry into the cloths. In one case which came under the author's notice good results were reported consequent on the removal and soaking of the cloths every week-end. This was additional to the use of an oil preservative. Some users report having employed twill cloths with 10% free alkali, the life being about three weeks, but it is desirable, if possible, to keep to 3% or 4%. A similar percentage of sulphuric acid should be satisfactory, though some users report that cotton cloths withstand 7% to 8% economically. Twill cloths are perhaps in greater favour than the chain weave, though some

users say the latter are stronger and give finer filtration. As far as the author can judge there is not much difference between the two, providing the cloths are properly chosen. The mercerising effect of alkali should not be forgotten, and if a cloth is to be used for alkaline liquors it is best not too tightly woven, as otherwise it may become relatively impervious. Further, for corrosive liquors those with the thicker threads seem to give the best results, as they will hold together in the press even after they have become quite rotten.

Linen is employed for the more open-mesh straining cloths, which are sometimes useful in the filter press when dealing with comparatively coarse sus-

Fig. 17.
Calcium tartrate ($\times 18$).

Fig. 18.
Jute cloth ($\times 18$).

pensions in liquors containing casein or other substances, which would rapidly render a mere compact cloth impervious. Jute and hessian cloths or sacking are often used instead of cotton, and are quite good with weak alkaline liquors, providing a very fine, tight weave is not requisite.

These cloths are also used as under-cloths, a strong coarse cloth being used to support a thin, tightly woven twill. This helps to protect it from damage at the joints, especially where there is likely to be trouble with rusting. Further, in such an arrangement the upper cloth may be sufficiently closely woven to stop very fine particles, and yet its thinness prevents its becoming too rapidly impervious. It is readily removed and washed, while the under-cloth, though strong and heavy, can be coarse enough to run freely for a considerable period. Filter paper may be used in-

stead of a fine upper cloth. It must be well supported, and should be of the crinkled variety, as this can give a little to the sag of the cloth. Paper has unfortunately the disadvantage that it may come away with the cake, but this is of no consequence if only the clear liquor is required.

Cloths with a swansdown surface are used for such purposes as the filtration of yeast, and are then protected from clogging by a superposed cloth of strong twill. It is, however, open to question whether they are any better than good twill cloths.

Fig. 19.

For strongly acid liquors there are a variety of cloths to choose from. One firm reports that camel's hair is satisfactory up to 30% sulphuric acid and 10% hydrochloric acid, while horsehair would stand 10% hydrochloric acid, but is not good for sulphuric acid. The same firm have used woven copper wire for 12% to 14% hydrochloric acid with a life of 4½ months, while the same wire cloth was satisfactory with 30% sulphuric acid. Wool or felt cloths will generally resist from 15% to 20% sulphuric acid, but are of little use for hydrochloric acid.

Asbestos will withstand any strength of acid or alkali likely to be put into a filter press, but is apt not to resist handling, and, further, is difficult to obtain in a sufficiently finely woven form. The qualities vary a great deal, and it is well to make careful tests before buying in quantity. On the whole, for strong acids, a good camel's hair cloth, if treated properly, has much to recommend it. A great deal, however, is sold as camel's hair which is of quite other origin.

With regard to wire cloth, in one case which came under the author's notice a twill nickel cloth was used for removing sodium sulphite from mother liquor up to 50% causticity. A sample of such cloth, 360-mesh, appears quite impervious to light, except when held at certain angles.

Cloths should not be allowed to dry on the press when out of use, but should be rinsed free of corrosive liquors and retained solids and kept moist. The former will cause rotting if allowed to dry in, while the solids will become hard and impervious. Repeated drying and wetting accentuates shrinkage. In a well-woven filter cloth for dealing with materials such as dyes, the threads, though stout, should be packed so closely that they touch one another at every point. Then again the cloth should be as free as possible from parallel dark streaks or "reed" marks or lighter portions indicating missed or broken threads. Occasional dark specks on a cotton cloth do not, however, signify.

Some users prefer to have the cloths shrunk before they are put on the press. With a well-woven cloth with small shrinkage this is not necessary with centre feed, top feed, or passages in external lugs. Where, however, there are ports near the bottom of the cloth it is usually wise to shrink the cloths before use. It should be noted that

the holes can be cut and the press clothed while the cloths are wet. In some cases boiling water should be used, but this, however, is not usually necessary, although it would have the effect of causing a cloth to filter clearly when it otherwise might not do so. The question of shrinkage is a difficult one, and depends on the weaving, though it may be said that the less compact cloths may shrink anything up to 7 or 8%, while more closely woven ones may shrink as little as 2½%. Something depends, too, on the quality of the cotton and the quality of the weaving, and instances are not unknown where two cloths of apparently precisely the same quality, texture, and weave may shrink very differently. On the whole, such valuable cloths as camel's hair are best soaked in mother liquor at the correct temperature before being put on the press, as if shrinkage occurs the strain on the cloth the first time it is used may seriously impair its life.

In dealing with many food products, and also in cases where the cloths become rapidly clogged, it is necessary to remove them at regular intervals for washing. The ordinary type of washing machine (fig. 19) consists of a vessel or outer casing within which revolves a perforated drum in which the cloths are placed. This drum is fitted with beaters, and revolves three times in one direction and then three times in the other to prevent roping of the cloths. The washing medium may be a weak solution of soda which can be heated by live steam, or a solvent may be employed. Another form of this machine has an independently driven squeegee inside the drum which acts as a shelf or lifter for part of the time and during the remainder compresses the cloths against a beater fixed to the drum shell. Another type of washer (fig. 20) consists of a tank constructed in wood or iron. A

Fig. 20.

squeezing block runs the whole length of the tank, and is suspended from hinges fixed on pillars attached to the machine. There are false sides to the trough which are sprung in such a way that they can give a little to the action of the squeegee as it rocks from side to side. The cloths are placed concertina fashion on either side of the squeegee and are first compressed and squeezed against the side of the trough and then released, being allowed to fall over and open out, after which the process is repeated. Such a washer is excellent for squeezing out obstinate dirt with a minimum of wear on the cloths.

The simplest device is a tank fitted with a steam circulating injector. This is satisfactory with light cloths and readily soluble precipitates.

Some theoretical and practical considerations in regard to rate of filtration, etc.

The design and efficient working of a filter-press installation depends on the material, the treatment

desired, and various factors of a mechanical nature.

The questions relating to the material comprise:

1. Quantity per hour.
2. Chemical properties.
3. Suitable temperature for filtration, and viscosity of liquor at that temperature.
4. Percentage of solids.
5. Size, shape of grain, and hardness of suspended particles.
6. The permeability of the deposit as affected by pressure, time, and flow.
7. Nature of first deposit on cloth.
8. Does deposit bind on to cloth, or will it fall readily away?

In regard to treatment we must consider:—

9. What extent of clarification is desired.
10. Is the cake or the filtrate of most value, and is a firm cake to be formed?
11. Must the material be washed, and, if so, how thoroughly?
12. Is it to be air dried in the press?
13. Are any special steaming, heating, or cooling arrangements needed?

The mechanical and other factors include:—

14. Practical chamber thickness.
15. Practical maximum pumping capacity.
16. Effect of various influences on the length of the discharging period.
17. Relative cost of various arrangements.
18. General layout in relation to remainder of plant.

It will be seen that it is not usually practicable to obtain exact information on the whole of the physical data involved. Fortunately trials with a gallon or two of liquor will enable the following data to be settled:—(a) Suitable cake thickness; (b) working pressure; (c) cloth; (d) time to make a cake, or rate of filtration; (e) nature of aids to filtration, if required.

Usually one or two tests will elucidate these sufficiently to allow those with proper experience to approximate to the most perfect scheme.

We will now consider various factors in detail, commencing with a mathematical treatment of such as are amenable to it. This is helpful to clear thinking, for while nothing can be a substitute for experience, it is not always realised what influence such factors as cake thickness and length of press have on output and economical results.

Where the solids build up with a perfectly rigid granular structure, the rate of flow is proportional to the pressure. It also varies inversely as the resistance of the cloth etc. and that of the deposited cake. The former is fixed, while the latter increases throughout the operation, being proportional to the total flow and the percentage of suspended solids. Sperry defined unit resistance as that which gives a flow of one gallon per sq. ft. per hour under a pressure of 1 lb. per sq. in. In the case of the solids a deposit of 1 in. was assumed in fixing the unit. The rate of deposition was settled as being unity when one gallon of filtrate flowing through 1 sq. ft. left a deposit of 1 in., there being 1% of solids in suspension. On these assumptions he derived the formulæ:—

$$\frac{dQ}{dT} = \frac{P}{R_m + R_t} = \frac{P}{R_m + \frac{RQX}{K}} \quad \dots \quad (1)$$

$$T = \frac{RX}{2PK} + \frac{R_m Q}{P} \quad \dots \quad (2)$$

$$Q = \sqrt{\frac{2PKT}{RX} + \left(\frac{KR_m}{RX}\right)^2} - \frac{KR_m}{RX} \quad \dots \quad (3)$$

where P=pressure. Q=gallons discharged liquor.
T=time in hours. dQ/dT =instantaneous rate

of flow. X=percentage of solids in liquor. t' =thickness of deposit in inches. K=rate of deposition. R=resistance of solids. R_m is resistance of cloth. (Cf. Chem. and Met. Eng., 1916, 15, p. 198—203.)

These formulæ all apply to constant pressure conditions, and do not include the period of diminished flow during consolidation of the cake. Since, for any series of such tests P, R, and R_m are readily kept more or less constant, while X is apt to vary, we may write $A=R/2P$, $B=R_m/P$, and $N=K/2X$ where N is the number of gallons to form 1 in. of cake; i.e., to deposit a layer $\frac{1}{2}$ in. thick on each cloth. A, B, and N are very readily found by a trial filtration in an experimental press, and we may simplify the original formulæ as below:—

$$\frac{dQ}{dT} = \frac{1}{AQ + B} \quad \dots \quad (1a)$$

$$T = \frac{AQ^2}{2N} + BQ \quad \dots \quad (2a)$$

$$Q = \sqrt{\frac{2NT}{A} + \left(\frac{NB}{A}\right)^2} + \frac{NB}{A} \quad \dots \quad (3a)$$

Such formulæ apply with very fair exactness over the greater part of many time discharge curves, providing these are taken under constant pressure conditions. We shall be mainly concerned with number (2a), as (3a) is only required when the ques-

Fig. 21.

Relation between time to form a cake and the strength of the mixture.

tion of cake formation is of no importance. The rate of flow dQ/dT diminishes with increased flow, as is well shown by the diminishing curve (fig. 26) described later.

We are now in a position to develop the formulæ with a view to applying them to the solution of the relation of the average rate of flow to the dilution of the mixture; of that of cake thickness to output; and of length of press to capacity—both absolute and in relation to prime cost. For the sake of simplicity we shall not consider closely the effect of the time required for final consolidation, or for filling the press initially, where the pump is of limited capacity. Nevertheless, the simple outline below will illustrate sufficiently the general tendencies.

Let F, be the time to form a 1 in. cake, the amount of filtrate being N gallons by definition. If a cake

t inches thick is to be obtained, the amount of filtrate is $Q=Nt$, and substituting this in (2a), the time F_t to form it is given by—

$$F_t = \frac{AN^2t^3}{2N} + Nt$$
$$= N\left(\frac{At^3}{2} + Bt\right) \quad \dots \quad (4)$$

From equation 4 we see that the time to get a cake is proportional to N (or the volume of filtrate to make a cake) providing the thickness remains

Fig. 22.

Relation between cake thickness and output for two extreme cases.

constant. It is not quite inversely proportional to the percentage strength of the mixture (although in many cases it may be nearly so) since a certain amount of liquid remains in the cake. Fig. 21 shows the theoretical relationship for a freely filtering material building a thick cake. The relation $N \cdot T$ is a straight line, while that of $X \cdot T$ is a curve giving values of T nearly inversely proportional to the value of X . The proportionality would be exact if X , in Sperry's formulæ, were calculated on filtrate, and not on total liquor. In practice, however, both these relationships may be somewhat altered by the greater consolidation of the cake when formed from weak mixtures, which may cause the time to form it to be lengthened out of proportion (*cf.* fig. 25 described later).

We will now consider the question of best cake thickness.

Substituting $M=AN/2$ and

$$m = NB, \text{ then}$$
$$F_t = Mt^3 + mt$$
$$F_1 = M + m$$

Let E be the time for emptying, which may be taken as constant for a given size of press, within reasonable limits of thickness. C is the weight of the cakes when 1 in. thick, and S the rate of

output over the whole operation, both measured in lb. per sq. ft. of area. Then

$$S = \frac{Ct}{F_t + E}$$
$$= \frac{Ct}{Mt^3 + mt + E} \quad \dots \quad (5)$$

S is a maximum with regard to t when $dS/dt=0$ (see fig. 22).

We have therefore

$$\frac{d}{dt} \left\{ \frac{Ct}{Mt^3 + mt + E} \right\} = 0$$

$$\therefore \frac{C(Mt^3 + mt + E) - Ct(2Mt + m)}{(Mt^3 + mt + E)^2} = 0$$

$$\therefore Mt^3 + mt + E - t(2Mt + m) = 0$$

$$t = \sqrt{\frac{E}{M}} = \sqrt{\frac{E}{F_1 - m}} \quad \dots \quad (7)$$

$$t = \sqrt{\frac{2E}{AN}} \quad \dots \quad (7a)$$

$$t = \sqrt{\frac{8EPX}{RK}} \quad \dots \quad (7b)$$

If we assume that the press is filled by a pump big enough to give the maximum initial rate of discharge, then the time taken to pump an amount of liquor equal to the volume of the press is proportional to t . In the above calculation all terms in t cancel out, and expressions (7) and (7a) are unaffected. The case is similar if we assume the cakes are washed at a fixed rate of flow. It may however be argued that there is a maximum washing pressure which should not be exceeded. In this case the time W_t for washing will be

$$W_t = t^2 W_1$$

where W_1 is the time to wash 1 in. of cake. Similarly it may be held that the time for final consolidation is approximately

$$k_t = t^2 k_1$$

where W_1 is the time to wash 1 in. of cake. Equation (5) now becomes

$$S = \frac{Ct}{(M + W_1 + k_1) \cdot t^2 + mt + E}$$

and the best thickness is

$$t = \sqrt{\frac{E}{M + W_1 + k_1}} = \sqrt{\frac{E}{(F_1 + W_1 + k_1) - m}} \quad (8)$$

$$\text{or } t = \sqrt{\frac{2E}{AN + 2(W_1 + k_1)}} \quad \dots \quad (8a)$$

Fig. 22 shows two curves drawn on the basis of equation (5) for certain conditions commonly met with. The existence of a best thickness for maximum output is clearly shown. In practice the use of this is limited on the one hand by the fact that if the cake is above a certain thickness it may consolidate and become impervious before it is fully formed. This will call for more work in emptying and drying. On the other hand, thin cakes will require more labour per ton, and so a balance of advantage must be struck.

Nevertheless the fact remains that for a material dealt with in a large press taking some time to discharge, thicker cakes are best if they can be formed. A small, rapidly discharged press will give most output with thin cakes if the filtration is fairly slow; if a thick cake can be formed rapidly it may however be satisfactory. This is entirely apart from any question whether thick cakes can or cannot be made. It is purely a matter of securing a proper balance between the filtering and discharging periods. It is also clear that if it is required

Fig. 23.

Relation of average output to length of press.

to wash the cakes at a fixed pressure, or if much consolidation is necessary, then thinner cakes are again desirable.

The cake thickness, however, is usually settled on practical grounds, determined solely by the thickest cake that can be made of suitable dryness, with a view to reducing labour costs. It is then of importance to know what length of press will give the best results. Let S_z be the average hourly capacity of the whole press consisting of Z chambers; C' the total capacity per chamber in lb. of cake; U the time in operating the closing gear per pressing, and V the time for emptying and re-closing one chamber. Then

$$S_z = \frac{CZ}{F_t + U + ZV} \quad \dots \quad (9)$$

Fig. 23 is plotted from this formula, and shows that after a certain length has been reached the addition of further chambers only slightly increases the output. This tends to reach a fixed limit, on account of the longer period the press is at a stand-still during each shift. If the cake is built quickly the press must be short or the discharging period will not be in balance. This will not increase seriously the labour cost, since this in the main is taken up in emptying and replacing the plates, only a small proportion being required for working the closing gear and manipulating the valves. It is only where the period of filtration (which in the present case may include washing and air drying) is very protracted, or the material can be emptied very rapidly, that it is economical to use a very large number of chambers. These considerations are strictly borne out in practice.

A further important question is that maximum output should be obtained per unit of prime cost. Let \mathcal{L}_z be the total cost of the press; \mathcal{L}_F the cost of the frame and heads, which includes the first chamber; \mathcal{L}_c the cost per additional chamber. Then

$$\mathcal{L}_z = \mathcal{L}_F + (Z-1) \mathcal{L}_c$$

The ratio of output to cost is therefore

$$\frac{S}{\mathcal{L}_z} = \frac{CZ}{(F_t + U + ZV)(\mathcal{L}_F + (Z-1)\mathcal{L}_c)} \quad \dots \quad (10)$$

Obtaining the maximum value in the usual way, we get

$$Z = \sqrt{\frac{(F_t + U)(\mathcal{L}_F - \mathcal{L}_c)}{V \mathcal{L}_c}} \quad \dots \quad (11)$$

Where

S =hourly output in lb.

\mathcal{L} =total cost of press. \mathcal{L}_F =cost of framework.

\mathcal{L}_c =cost of each additional chamber.

C' =lb. of cake per chamber. Z =number of chambers.

F_t =length of filtration period, including washing etc.

U =time in hours to work gear and valves per operation.

V =time in hours to empty and replace one chamber, including an average allowance for clothing.

Taking a 38 in. plate and frame press, we may assume that the time for working the closing gear, operating valves, pumps, etc., is 20 mins.; and for emptying, say 2½ mins. per chamber. Assuming 3 hours is occupied in getting a cake and substituting current values for \mathcal{L}_F and \mathcal{L}_c , we find the best number of chambers is 32. Hence large units would best be made up of this size press, though for installations of only a single press it might not be worth while to limit the size.

Fig. 24.

Relation of length of press to output per unit prime cost for a 38 in. sq. P. & F. cast-iron press.

Fig. 24 has been drawn on the above basis for three varying periods for filtration and washing. For the slower ones more chambers are seen to be economical, but the slope of the curve varies very gradually for the longer periods. Even when 9 hours are required for filtration we see that it is hardly worth while going over 40 chambers, though the best figure is given by calculation as 54. If discharging were slower, then shorter presses still would be indicated. This would also be the case with more quickly filtering liquors. Recessed presses, or those with wooden plates, would preferably be rather longer, as the cost per chamber is proportionally less. Should the closing gear be elaborate and slow to work, the presses would be best if slightly longer in the case of rapid filtration.

It is difficult to obtain sufficiently exact figures on which to base a similar calculation in regard to the most economical size of plate. The laws would, however, almost certainly follow the lines of figs. 22 and 24, and there would be a definite size for maximum average output, and for maximum output in relation to prime cost. The latter consideration would almost certainly indicate a somewhat smaller size than the former. The labour in discharging one chamber may be divided into (a) mov-

ing plate, (b) dropping the cake, (c) cleaning the cloths, (d) renewing cloths, (e) cleaning passages and ports.

Now (b) and (c) are fairly independent of the size of plate, (a) is more or less so up to a point, after which it increases very rapidly, (e) is directly proportional to the area, while (d) is more or less so, depending on the type of plate.

If the filtering period is long, larger plates will be economical, but in this case one would not expect to find the line of demarcation very strongly defined. If the cleaning of the cloth is the major part of the operation, this will tell against any

Nottingham. Fig. 25 shows a family of curves relating to spent lime suspensions of various strengths. The total discharge is plotted against time, each test being made with a frame 4 in. deep, at a constant air pressure of 70 lb. per square inch. Readings were taken every minute, and filtration continued till three constant ones were obtained. The law connecting time and flow is well illustrated. In the case of the weakest suspension this is $T = 1.19Q^2 + 0.8Q$ (or $T = 3.57Q^2/2N + 0.8Q$) where T is in minutes. The effect of the consolidation period is shown by the difference between the upper part of the actual curve, and the dotted line repre-

Fig. 25.

Filtration of caustic liquor containing various amounts of spent lime.
4-in. cakes, 70 lb. air pressure.

marked economy in the use of big plates, but if the cakes drop cleanly away, then the best results are likely to be obtained with large sizes. Wood plates, on account of their lightness are economical in larger sizes than iron ones. As a general rule 38-in. or 40-in. plates are quite large enough, and even these do not always show any marked reduction of labour as compared with the 32-in. size. The chief advantage of very large sizes usually lies rather in the saving of space.

We may now pass to a consideration of one or two test curves, taken in the small scale plant department of Messrs. Manlove Alliott and Co., Ltd.,

senting the theoretical one. The maximum reading in gallons for each case is, of course, proportional to N , and on reference to equation (4) we see that the time to get a cake should also be proportional. If this holds, all the curves should end on the same straight line passing through the origin. The four tests with stronger suspensions agree well with this, except that the line is displaced a little to the right. This is no doubt due to some residual consolidation effect. The curves for the weaker suspensions vary markedly from this line, taking longer in proportion. On inspection the cakes were distinctly dryer in appearance, and the percentage

moisture was found to be slightly less. Apparently the slower filtration was due to the fact that the lime particles had time to settle down more compactly; and it is probable that the smaller ones were gradually washed from between the larger (cf. fig. 28) to form a more compact and impervious layer near the cloth. The distinction between the two rates of flow is very marked, but further trials would probably show that they merge more or less gradually.

The tests on both the lime and the dye were made with the same cloth, and exhibit clearly how different are the resistances of the cakes, and how markedly the resistance of the cloth varies when the latter is used under altered conditions.

The permeability and dryness of a filter cake depend on the size and shape of the particles, and especially on their texture, whether firm or otherwise. Comparatively coarse, hard grains are favourable, as the capillary passages are large,

FILTER PRESS.

Fig. 26.

Time discharge curves for Direct Yellow.

Fig. 26 shows a time discharge curve for a sample of Direct Yellow recently tested by the writer. In this case a complete 1 in. cake was formed at a very early stage, though, of course, it was extremely soft. This was tested and confirmed by two separate trials, at the end of which the press was opened while still draining freely. The curve itself is the result of a third trial carried on as long as seemed worth while. In this case, although the conditions under which the solids are deposited are so very different from the former instance, the curve agrees well with $T = 115.4Q^2 + 25Q$ (or $T = 255Q^2/2N + 25Q$) right up to about 80% of its total flow. Curiously enough, where it departs from the formula, the curve shows a quicker rate of filtration, and this divergence may be due to some slight subsidence of the suspended solid matter, so that during the latter portion a comparatively weak liquor might have been fed to the press. The mixture was, however, kept agitated during the whole test.

On the same chart has been plotted a curve showing the rate of filtration, at every moment during the test, as compared with the horizontal line giving the average rate of flow over the whole period. Nearly half of the substance is fed in at a considerably higher rate than the average, while it will be seen how slowly the flow from the taps comes to an end as the cake is gradually consolidated.

and high pressure can be used. It is not, however, desirable that the grain should be so coarse as to cause rapid settling. If this should happen in the press a cake of uneven quality would be formed, which would be unfavourable for washing or air drying. It might be difficult also to secure a clear effluent, as is explained later.

A great part of the art of filtration lies in the control of the nature of the suspension. In this the microscope is a useful aid. Higher powers than $\frac{1}{2}$ in. objective, and 9 times eyepiece are not usually necessary, but for substances like anthracene or β -naphthol a polariscope is useful in rendering the crystals visible. If the particles are mounted in liquor they can be made to separate or turn over by pressing with a sharp point on the cover glass, and thus their real shape and the compactness of their grouping may be judged. By this method, for instance, it can be seen quite clearly that β -naphthol particles consist of large, though very thin, flat plates, while particles of anthracene in suspension in oil, having very much the same appearance while still, are really somewhat irregular nodules which are more or less of equal shape when viewed from any angle.

Fig. 27 shows the previous sample of calcium sulphate magnified to 250 diameters. It will at once be seen what a coarse open meshwork will be built up in the cake. Such a shape and size of crystal is, of course, extremely free filtering, and

is very favourable to good washing results. The needles shewn run 0.001 in. in length, or even larger, and the breadth is about 0.0001 in.

Fig. 28 shows on the same scale a suspension of calcium carbonate. Many of the crystals have

Fig. 27.
Sulphate of lime ($\times 250$).

Fig. 28.
Spent lime ($\times 250$).

Fig. 29.
Sludge from soap lye ($\times 250$).

aggregated to form comparatively large firm lumps, but the scattered particles will give a fairly good idea of the size and shape of the individual unit. Numbers of these are only 0.0001 in. in diameter, while some are even less. This material

is, however, quite free filtering, as will have been gathered already. This is due to the fact that the particles are hard and angular, with no trace of sliminess or gummy matter, and the aggregated clusters are sufficiently firm and numerous to keep

Fig. 30.
Benzopurpurin ($\times 250$).

Fig. 31.
Direct Yellow ($\times 250$).

Fig. 32.
Grey filter paper ($\times 250$).

the cake open. The precipitate from soap lye presents quite a different appearance (fig. 29). Even in the photograph the shapeless outline and scummy nature of the particles are indicated, suggesting good results would be secured by not too

high pressures. Fairly rapid filtration may, nevertheless, be obtained, and probably this is due to the comparatively large size of the particles concerned. A somewhat different appearance is presented by the various aniline dyes. In the case of the substances previously mentioned, all the particles appear to be at rest, but in the case of dye-stuffs a number are often to be seen in motion. If, for instance, Benzopurpurine is examined in suspension in water, assuming the preparation has been freshly made up or recently agitated, each particle would seem to be separate, assuming a thread-like form 0.0002–0.0001 in. long by about one-tenth of this in diameter. Some preparations are even smaller, while the threads are not rigid but curl and uncurl in addition to having a distinct oscillatory or Brownian movement. After a long period of rest all movement will have temporarily subsided and the separate particles will have massed themselves together in such a manner as shown in fig. 30. Filtration at comparatively low pressures is clearly indicated.

The agglomerated and motionless condition is the more favourable to good working. The particles may also be seen to be of somewhat larger dimensions than when they are scattered and freely moving. Since this state can be brought about by the presence of an electrolyte such as salt, it is good to retain a suitable proportion of this if market conditions, etc., will permit. Naturally cake formation is apt to be slow at best with deposits of this type, and closely woven cloths are necessary. Washing is usually out of the question. This is partly due to the high resistance of the cake, and to the fact that as soon as water penetrates the mass it removes any electrolyte present, and the dye particles then assume a still more intractable nature.

Fig. 31 shows a sample of Direct Yellow. This gives a freer flow and is more readily retained by the cloth, as is indicated by the large size of the particles and the way in which they are massed. Fig. 32 shows a sample of filter paper on the same scale for comparison.

Before leaving the subject of quality of grain, it may be of interest to mention a curious property of many filter cakes, due to the shape and hardness of the particles. Such cakes appear firm and comparatively dry and free from surface moisture when first discharged. If a small piece is shaken in the hand it becomes sloppy, and a distinct amount of free surface moisture appears. This is due to the fact that the particles are deposited initially in any order, but when shaken assume their most compact grouping, causing the moisture in the interstices to appear at the surface. Further, as was shown by Osborne Reynolds (Scient. Papers Nos. 50–51), such hard material does not necessarily assume its most compact grouping under the application of pressure, providing this is not sufficient to crush the grain. This supposes the existence of an elastic boundary, which is provided by the cloth. This property Reynolds termed "dilatancy" (fig. 33). It is so marked that if a football bladder is filled with fine sand and water, and fitted with a glass tube in the neck, excess water will not be forced out, but is actually seen to be drawn into the bag when the latter is squeezed.

Some liquors contain particles so fine that they cannot be retained on the usual filter cloth, unless of a very close texture, while in other cases, such as sugar scums and some varnishes the liquor is so slimy that an impenetrable layer is speedily formed on the cloth and it becomes impervious. In such cases various aids to filtration can be used. The requirements for such an aid are as follows:—

- (1) It must form a readily permeable deposit.
- (2) It must not be difficult to keep in suspension.

(3) The capillary pores between the particles must be sufficiently fine.

(4) If very fine scummy particles are to be removed, it must have a maximum of surface, and its nature must be such as to favour adsorption.

(5) It must have no injurious action on the material being filtered.

Among such substances may be mentioned calcined fuller's earth, diatomite, and various other refined fossil earths, large crystals of calcium sulphate, charcoal, wood meal, cotton meal, etc. In some cases it is actually possible to produce a lime precipitate in the liquor before filtering, with the result that the slimy particles are covered with a lime deposit and the cake rendered more open and permeable.

Fig. 33.

In this connexion it should not be overlooked that the coarser particles in a precipitate may assume the nature of a filter aid towards the smaller ones, which would not be retained by the cloth if the whole precipitate were fine. Hence it may be difficult to get clear filtrates if the larger particles are allowed to settle out in the filter press owing to insufficient pump capacity, etc.

For fine clarification the cloth may be given a very thin coat of the filter aid by pumping in a suspension of the latter before commencing to filter. It is also useful when mixed with the liquor, as it not only helps to give a clear filtrate, but builds up an open structure in the cake, thus permitting a more rapid flow where slimy matter has to be removed.

The following weights of dry solids per cubic foot of press capacity—together with the moisture in the cake—may be of interest. They are all taken from ordinary large scale practice. They should, however, be regarded only as a guide, as very different results are sometimes obtained between one factory and another. Those moistures marked with a * have been reduced by means of blowing air through the press:—

Material.	Dry weight per cb. ft.	Moisture, %.
Orange chrome	340	5
Zinc chrome	200	7
Lemon yellow chrome	46	55
Para Red	53	30
Prussian blue	15	60
Magenta lake	20	60
Wolfram tin fines	136–160	10–17
Tungstic oxide	104	14–21
Spent lime	57	38
Calcium sulphate	42–55	40
Anthracene	29	46
<i>β</i> -Naphthol	47	30–40
Sulphur black	42	40
Sulphur blue	59	32
Wool red	19	60
Direct brown	35	50
Benzopurpurine	38	35–40
Congo red	42	50
Triacid violet	23	30–35
Orange II	20	40–45
Sewage sludge	30	60
Sludge from soap lye	30	60

Cake thicknesses vary from $\frac{1}{8}$ in. up to 4 in. or even 6 in. in the case of very permeable deposits. Some samples of calcium sulphate and carbonate will build up to the higher figures. In many cases 2 in. is considered a good thickness, even for the above substances. Colours and dyestuffs are usually

filtered in presses having chambers 1 in. to 1½ in. thick. Materials are not unknown which will build a layer only a few hundredths of an inch in depth. In such cases cake formation is impossible, and the excess liquor has to be drained out of the press.

It is well worth while for users to study and test the best pressures for feeding their particular grade of material. Too many operators are satisfied that things are right so long as a clear effluent is obtained, and it is not realised that better results are often obtained by relatively low pressures, except perhaps in the last stages of the run. In relatively few cases does high pressure produce proportionate results either in rate of flow or weight and moisture of filter cake. In fact, it may reduce the rate of flow or stop it altogether by destroying the open structure of the deposit.

½ gall. per sq. ft. per hour or even less. Some vegetable oils have rates of flow varying from 1 to 8 galls. per sq. ft. per hour, but in other cases these figures may be halved. In one case soap lye after acidification filtered at the rate of 4 galls. per sq. ft. per hour, and the same liquor after neutralisation gave a flow of about double this amount. This filtration was carried out at a pressure of about 20 lb. per sq. in., never exceeding 30 lb., whereas it is sometimes considered that pressures of 100–150 lb. are necessary for this material. In another case the lye was filtered only after neutralisation, and the rate of flow was 5½ galls. per sq. ft. per hour under a gravity head of only 20 ft.

In the case of sewage, rates will vary from 3 galls. down to ¾ gall. per sq. ft. per hour, the usual figure being about 1½, and the pressure

Fig. 34.

Correction of time discharge curve for cake volume and pump capacity. Rapid filtration.

In ordinary filter press work pressures may range from, say, 150 lb. per sq. in. down to 20 ft. gravity head or even less. The higher pressures are only suitable for very viscous liquors containing hard solids of a hard granular nature. Where viscosity is small pressures of 70 to 100 lb. are usually ample for granular or fibrous suspensions, while many materials of only a tolerably open texture are dealt with very satisfactorily at 40 to 60 lb. Dye-stuffs, colours, etc., and other materials of a very fine nature are often advantageously handled at half this pressure or even less. Prussian blue, for instance, is generally dealt with at 30 ft. gravity head.

Even when higher pressures are justifiable it is well to start the operation at a comparatively low pressure in order that the first layer of the cake may be open and porous. For slimy materials the preliminary feed may well be under a low gravity head. Once a good layer has been formed there is a tendency for the particles to interlock, and they are then less liable to be forced through the cloths by a higher finishing pressure.

Rates of filtration are very varied. They are highest where large quantities of liquor containing small amounts of solids are being handled, providing that it is not necessary to form a cake of high solidity. In such cases it pays to clean the press out as soon as the rate of flow falls off. In clearing a watery liquor from impurities and dirt, rates of from 15 to 30 galls. per sq. ft. per hour are often obtainable. On the other hand, viscous materials, such as varnish, may only give a flow of

80–100 lb. per sq. in. For the majority of dyestuffs the range is about 2 galls. per sq. ft. per hour down to ½ gall., and in very difficult cases one gets down to a flow as little as one-tenth of the latter amount.

Methods of Feeding the Press.

Fig. 34 illustrates one method of fixing a suitable pump capacity. A time-discharge curve, ACB, is obtained in the usual way, the dotted line, AB, representing the total average discharge. It is presumed that the original curve is obtained experimentally from a small-scale test, in which case the rate of flow is generally determined entirely by the press and not by the pump. It is further assumed that the substance is one in which it is permissible to use pressures rapidly approaching the maximum in the early stages of the test. A curve obtained in this manner needs to be corrected for the volume of the cake itself and for the employment of a pump of a practical size. In the instance given, AB corresponds to the steady discharge of a pump having a capacity of 6 galls. per hour per sq. ft. of filter area. The volume of cake is 1.04 galls. per sq. ft., and a line GY is drawn to represent this at a suitable distance below the horizontal axis. The line DU is parallel to AB and tangential to the discharge curve. It represents the steady flow of the pump, pumping up to the maximum pressure at which the relief valve is set, which is reached at point H. The distance of D from the vertical axis represents the extra time

per operation when a pump of this capacity is employed. The position of the point E gives a similar figure for a pump of double this capacity, and G for a rather smaller one. The times for washing, air-drying and emptying the press have also been added to the chart, and this enables a reasonable judgment to be made as to what correction should be allowed for the pump. On rates of filtration thus obtained the most economical size of press and pump may be calculated, due attention being given to the effect of any variation in the size of press on the discharging period.

Such a diagram is useful in so far as it gives a clearer perception of the various problems which enter into the determination of pump capacity and total output. In some cases, where filtration is free almost up to the last moment, and the pump is not too large, it is possible to force the liquid through at the full capacity of the pump during the whole filtration period, thus avoiding waste flow through the relief valve. This generally entails

of pipe between the press and any of the valves are to be avoided and the pressure relief valve is best brought up near to the feed valve where possible to avoid clogging or settlement in the feed pipe during the final consolidation period.

In addition to the pump connexions, steaming valves have been indicated both on the feed inlet and wash water outlet passages together with an air connexion for blowing air into the cake and a drain connexion on the bottom passage to serve as an outlet for any liquor blown off by this means.

The diaphragm type of pump (figure 36) is a very good method of dealing with thick sludges and is also useful for acid liquors, as it lends itself to coating with lead or vulcanite or other materials on all parts except the rubber diaphragm.

A single-acting pump is often a necessity for small duties, but it is really the worst type, as even with a large air vessel pressures are apt to be fluctuating. For larger duties double-acting, or better still, treble-acting pumps, are desirable.

somewhat slower filtration than might otherwise be obtained.

Fig. 35 shows the full connexions of a thorough washing filter press fed by a vertical plunger pump. It will be noticed that the air vessel is much larger than usual in order to minimise pressure fluctuations. In filtering sensitive materials with a single-acting pump this point should not be overlooked. A pressure gauge is desirable, as it enables the operator to see whether the pump is working properly and the pressure is being put on at a suitable rate. An automatic relief valve, set at the maximum pressure, is placed on the pipe between pump and press, and the liquor from this returns into the pump feed connexion. A re-circulating valve, worked by hand, is sometimes provided so that the first layer can be placed comparatively slowly on the cloths. Connexions are also shown for pumping wash water into the press, and in this case it is necessary to flush the pump and connecting pipes before washing. It is preferable, however, to have separate arrangements for the water supply, as the best pressure for washing is not as a rule the pressure at which the liquor should be fed to the press. Generally speaking, more than enough pressure will be got from the water main or even from an overhead tank. In practice dead lengths

Special pumps are also constructed in such a way that the effective stroke is decreased with increasing pressure, thus diminishing the rate of flow and causing the pressure to be put on gradually. The duplex steam-driven type of pump is a good pattern, as it gives a reasonably even feed and is to a large extent self-adjusting to meet increasing pressure. Even this type is generally fitted with a relief valve and large air vessel. The ram should be of the outside packed pattern where packings are likely to require frequent attention.

Undoubtedly the best way of charging the press, where gravity feed is not applicable, is to use an egg and force the slurry in by compressed air. Unfortunately this method is expensive except where a large number of presses have to be supplied or duties are large. Valve troubles are avoided, the flow adjusts itself automatically, and the pressure is perfectly even. On starting to filter the full initial flow is obtained at low pressure with a minimum amount of air. If several batches are necessary to fill the press it is only the latter ones which need air at the maximum pressure.

Figure 37 shows a wood press fed by a ram situated in a chamber below the floor. The feed pipe from the supply tank on the upper floor has a connexion to the press for initial filling by gravity,

thus economising air. For heavy sludges the air inlet pipe may be taken to the bottom in order to give a stirring effect, though for very heavy precipitates an agitating gear should be fitted. Rapid filtration in early stages is very valuable in the case of materials having a strong tendency to settle.

Sectional arrangement of vertical diaphragm pump.

capacity of their press during the earlier stages. This is an important point to consider when the best washing results are desired.

In a case which recently came under the writer's notice feeding with a small pump gave cake which could not be washed below 2% soluble matter with any amount of time or wash water, but when a ram with agitating gear was installed the cake could be washed to under 0.2% with but little trouble.

Washing in the Filter Press.

Washing can be carried out with great advantage in the filter press. The simplest method is to force water in through the feed passage. This is best done in the plate and frame type, and it is preferable that a solid cake should not be formed, but that a space should be left between the layers built up on each cloth. Here a bottom feed is advantageous, as the strong liquor can be drained from the chambers prior to washing, though in the ordinary type it can generally be removed by air pressure. It is possible to wash this way in any plate and frame press or even in recessed presses, although they may not have been specially designed for the purpose. If a solid cake is not formed it is the only practicable way except re-lixivation.

The trouble is that owing to sedimentation the cake is apt to be thicker at the bottom, and in order to keep the two sides from touching space may be wasted at the top. Further, the press capacity is diminished and more labour is necessary in emptying. In some cases, however, solid cakes can be rough washed if they are sufficiently permeable. General reports from users appear to show that more wash water is requisite, but this would depend very much upon the manner of the operation. This method of washing is usually referred to as "simple" washing. Another consists in forcing the water from one side of the cake to the

ment, and in such cases where the grains are not uniform it will be found best to instal a large egg or receiver, in which the whole batch can be thoroughly stirred up and forced rapidly into the press. This method will give a more uniform and permeable cake than would be formed by a pump, more especially as most users are averse to paying for a pump sufficiently big to take care of the full

other, and may be referred to as "through" washing. It is also called "back" washing, as the water is admitted to the back of the cloths.

Fig. 38 shows this method applied to recessed plates. The wash water inlet passage forms a continuous channel in an upper corner of the rims. It has inlet ports to each alternate plate, on which the filtrate cocks must be closed during washing.

The water enters behind the cloths, passes through these and the cakes to the back of the cloths on the intermediate plates, the cocks on which have been left open to permit it to escape. This is sometimes called "tap washing," and its chief merit is its

Then, again, the washings should be taken out at the top of the press, so that there is exactly the same pressure tending to force the water through the cake whether this be measured at the top or at the bottom. The importance of these factors

Fig. 38.

Recessed plates. Washing type.

simplicity, as only one special passage is required. One disadvantage of an internal feed is that a soft core will permit shortcircuiting, while a hard one may not get washed properly. For the very best results plate and frame presses should be employed, owing to the even thickness at the cake at the edges and the fact that any soft material in

will be better understood when it is realised that comparatively low pressures are best for washing purposes, as will be seen later. Except where due provision has been made, time will be required under such conditions to force trapped air out of the press, and in addition any unbalanced hydrostatic head (due to unrestricted draining on the

Fig. 39.

the feed passage is isolated. Further, provision should be made for the escape of any air which may have leaked into the space behind the filter cloths at the conclusion of filtration, as this may prevent the water flowing through the upper portions of the cakes. Even ordinary "tap washing" is distinctly improved by the provision of air cocks.

outlet plates) will aid in causing a disproportionate amount of wash water to percolate through the bottom of the cakes.

A filter press in which all these points have had attention may properly be described as a "thorough" washing press (fig. 39). The illustration shows wood plates and frames constructed on

this system. At the conclusion of pressing all the filtrate taps are shut off and wash water is admitted to the enclosed channel at the bottom. This passage connects by ports to every alternate plate and permits the water to rise behind the cloths on these, driving the air before it into the special air channel which connects with the wash inlet plates only. As soon as there is any flow from this

This permits plain cloths without holes to be used, and there is no difficulty in fitting and keeping them in place. The joints on the lugs are often made by cloth sleeves, which are slipped over them. These must be changed with the cloth, and for that reason rubber joint rings are often preferred. These may be let into special grooves around the wash passages, or may fit inside as shown in fig. 41.

PLATES WITH EXTERNAL LUGS

Fig. 40.

it is shut off, and the water must then pass horizontally through the cakes and cloths to the intermediate plates, where it rises in the grooves till it escapes into the enclosed outlet at the top. In this way provision is made for as perfect a displacement as possible of the strong liquors in the cake. An even better arrangement would be to have wash outlet cocks fitted on the tops of the plates, deliver-

Hydraulic lipped rings are shown, but quite good results may be obtained with plain rings, which should be just a push fit inside the channels. Rubber is not always permissible, and a more expensive press is required than if cloth sleeves are used.

In any event the cost of outside lugs is only justified where the filtering medium is subject to frequent washings or renewals. Normally the cloth is kept in place by adherence to the plates once it has been used, so that even where passages are in the rims no difficulty is experienced in keeping the holes in their right positions. If the cloths last a reasonable time and proper arrangements are made for cutting the port holes, the cost of this is small in proportion to the work done. A useful type of plate has two external passages in lugs which form part of the handles (see fig. 42). One of these is a feed passage, the other the wash water inlet passage. This form permits the outside lug plate to be made more cheaply, and in a form very convenient for manipulation.

Now, assuming that a press has been selected with all facilities for washing, as described above, and care has been taken that the filtering surface has been kept free and unchoked, giving the wash water access to every part of the cake, there are

Fig. 41.

ing into a special trough, as this would permit any chamber giving muddy washings to be shut off at will. In general practice, however, enclosed outlets are found more convenient and perfectly satisfactory.

An interesting point about presses of this type is their extreme adaptability. There are a dozen possible variations of the washing connexions alone, since any passage can be used as an inlet, without counting possibilities in regard to steaming, air-drying, etc. The chief methods of washing are, however, ordinary thorough washing as above; washing in reverse direction, either through the enclosed outlets or through the taps and ordinary simple washing as first described. The wash water and air passages can be used as enclosed filtrate outlets. It is obvious that air, steam, or water may be admitted to the wash passages when the press is empty, but closed up ready to restart. By this means the cloths are given a reverse washing, and may be made to last longer before clogging.

In the case of iron plates, these wash passages are made either in the plate rims or can be with advantage in external lugs (fig. 40).

Fig. 42.

still other factors essential to satisfactory results. These are:—

- (1) Care must be taken to secure a well-formed cake.
- (2) The cake must be of as coarse a grain as is possible, without causing settlement in the press, and the various grades of particle must be uniformly distributed.

- (3) The washing pressure must not be too high and should not fluctuate. It should be applied as quickly as possible after the cake has been formed.
- (4) Care must be taken that the press is worked properly and especially that the air-taps are made use of.

Economical washing depends on even displacement, and good practice results when this ideal is approached as nearly as possible. If the cake is not complete, obviously there will be gaps, through which water can pass. Further, if the deposit is soft and not properly compacted such gaps may readily be formed during washing, while if this operation is delayed some cakes tend to sag a little and do not fill the chamber up to the top. The frames may be fitted with an internal rib or fin to counteract the effect of this, but some users consider there is more difficulty in cleaning out the cake. Then if the grain is too fine it will be difficult to get the wash water to penetrate without undue pressure, which may cause channelling and short circuiting. In such cases adsorption effects are also likely to hold back soluble matter in spite of even the most perfect washing. If the grains are reasonably coarse they will be more permeable, and will have less surface to retain strong liquor. A truer and quicker displacement is then likely to result. If they are not of fairly uniform size, the coarser ones will probably have settled to the bottom of the chamber, and the wash water will pass in preference through them, giving mixed or weak washing. If the particles themselves are porous, time will be needed to extract the absorbed soluble matter, quite apart from surface effects.

Finally, high pressures should only be applied with caution, as these may cause channelling and short circuiting. The lowest which will give a reasonable flow should therefore be used. The supply must be steady, and a gravity feed or a connexion to the town water supply is usually preferable to the use of a pump, where either can be employed. While the best results are usually obtained at pressures much less than those in general use for consolidating the cake, it should not be overlooked that the filtrate has only to penetrate half of its thickness, while the wash water must pass through the whole depth of the consolidated mass. In order that washing may not be too prolonged, the best cake thickness is usually somewhat less than for plain filtration. Good supervision is necessary, as one often sees presses provided with all the appurtenances for scientific washing being handled in a most unintelligent fashion. The author has seen thorough washing presses with practically every valve and tap open except the air cocks, while wash water was being admitted behind the cakes and into the feed passage at the same time. Needless to say, in such an instance every ounce of pressure that could be got out of the mains or wash pump would be applied.

Fig. 43 shows some tests carried out by the author on the washing of very weak caustic solutions from spent lime cake. It will have been realised from the photomicrographs that many of the particles in such a cake are extremely small, and consequently there is plenty of surface to hold back traces of alkali. Nevertheless, in these experiments almost theoretical results were obtained, the strength of the washings keeping right up to or quite close to the original strength till a volume equal to that of the liquor in the cake had been displaced. It will be observed there is still a fair strength of washings coming off even after this point has been reached, this being doubtless due to residual liquor behind the cloths and in various passages immediately connecting with the press. Adsorption, and possibly capillary effects in the case of the clusters, doubtless play their part. The

tests were made with a 4-in. cake at 20 and 40 lb. per sq. in. and a 2-in. cake with 20 lb. per sq. in. respectively. Not a great deal of difference is observable in the form of the curves. They all fall practically down to the specific gravity of the pure wash water after an amount equal to the total volume of the cake has been employed.

Fig. 43.

Washings calculated as percentage volume of mother liquor in cake.

Washing weak caustic soda solutions from carbonate of lime cake (experimental).

Of course such results can hardly obtain in large-scale presses unless a good deal more care than usual is observed. In dealing with carbonate of lime one firm reports the use of about $1\frac{1}{2}$ volumes of wash water (compared with cake volume) at 15 lb. pressure to wash cakes $1\frac{1}{2}$ in. thick and 24 in. square, the residual free alkali in the cake being 0.2% or slightly under on a fair average of the cake. The time for washing was about ten minutes. In another case sulphate of lime cakes 2 in. thick were washed free from all but a trace of a certain organic salt with $1\frac{1}{2}$ volumes of washings. In dealing with gold slimes cakes about 36 in. square by 1 in. to $1\frac{1}{2}$ in., of practically pure silica, were washed free of cyanide solution with about $2\frac{1}{2}$ volumes of water compared with the volume of liquor in the cake. Sugar scums, filtered by the aid of kieselguhr or lime admixtures, would require about $1\frac{1}{2}$ to $1\frac{1}{4}$ cake volumes.

If the deposit contains slimy or colloidal matter in any quantity, and the particles are fine, much more water in proportion will be required and the washing time will be protracted. Certain classes of dyestuffs cannot be washed for the reasons previously stated when discussing the photomicrograph of benzopurpurine (see p. 276 r).

Fig. 44 shows the relation between strength of washings and time taken in freeing from soluble matter a carbonate of lime cake contaminated with colloidal silica, which tended to wash out on to the cloths and choke them. In this case it will be seen that to economise water washing has been carried out in three stages, one with a strong liquor, followed by a second wash with a weaker solution, and, thirdly, with pure water. The volume of washings in each case was about $1\frac{1}{2}$ to $1\frac{1}{4}$ times the volume of the cake. In treating a difficult wolfram tin slime, from which the coarser particles had been separated, only the fines being taken to the press, a head of only 4 ft. of water was used for

washing. One and a-half cake volumes of washings left 1% of soluble matter, 24 volumes left 0.16%, while 3 volumes left 0.08%, or occasionally

Fig. 44.

Washing carbonate of lime filter cake (contaminated with colloidal silica).

only a trace. With an especially difficult sample consisting of practically pure MnO and FeO , somewhat over twice this amount of wash water was required, the residual soluble matter being 0.3%.

Temperature control; steaming; hot and cold presses; air drying etc.

Viscosity is an important factor, as the rate of flow varies in inverse ratio. Since small increases in temperature may reduce viscosity in much greater proportion, the wise user will not overlook this means of increasing output.

various types of plates which may be used. A very satisfactory form is to cast some simple passages in the plate to take steam at a few pounds pressure. The steam enters and the drain leaves by continuous passages similar to those used for washing. This is quite sufficient to keep the plates hot and counterbalance the loss of heat from the press. Alternatively a coil of pipe may be cast in the plates, but this is an expensive method and does not give any more satisfaction. Where the utmost application of heat is necessary the plates may be hollow throughout. This construction is also very useful where liquors have to be kept cool while they pass through the press, as the greater area of directly cooled surface counteracts the somewhat low temperature head available for heat transference in such cases. It is not desirable, however, to look upon the filter press as a heating battery; the devices just described are only intended to prevent the temperature of the liquid dropping (or rising) unduly.

In order to get drier cakes air may be blown through the feed passage or from one side of the cake to the other, using the wash passages, in which case it is better to take in the air at the top of the press and bring it out at the bottom, so as to allow of thorough draining. In the case of a permeable substance the mixture can be substantially reduced by this treatment in a very short time. In one case spent lime cakes were brought from 38% moisture down to 20% or 22% in about 4 minutes with air at $82^{\circ}C$. Air blowing is equally useful in the case of finer materials, but much more time is required. A pressing of β -naphthol was reduced from 60% moist to between 30% and 40% by 1 hour's treatment. Two hours is a not unusual allowance for dyestuffs, but occasionally it is considered worth while to continue for far longer periods. Where a separate air-supply is not available, the feed pump may be allowed to run for a longer or shorter period,

INTERNALLY HEATED OR COOLED PLATES.

Fig. 45.

If the rate of flow is fairly large, the liquor itself will usually keep the press sufficiently hot. A steam valve is often fixed on the feed inlet, and this may be employed to pre-heat the press. It is also a very useful adjunct for steaming the cake and cloths through at intervals to keep them warm and render them more permeable, as in the case of wool grease recovery. In dealing with cakes of fuller's earth from the refining of lard, oils, etc., it is usual to steam these well through at the conclusion of filtration. This is best done one chamber at a time to concentrate the effect. After such treatment the cakes will usually drop out in the form of a loose meal, practically dry to the touch. They would then contain, say, 14% of lard, but reports are sometimes received of as little as 10% of grease remaining in the cake.

Where filtration is slow, the press may require special heating arrangements, and fig. 45 shows

sucking air and forcing it into the feed passage with satisfactory results in many cases.

Discharging the filter press.

Labour costs are dependent upon the press itself, the general arrangement of the plant, the grade of material, and local conditions.

While small plates mean that a greater number have to be handled, very big ones are difficult to move rapidly and, generally speaking, medium sizes give the best results. Wood plates may be somewhat larger on account of their lightness. If the material drops away cleanly from the cloth, and especially if the plates are of the simple recessed type with central feed, then larger sizes may still be economical in labour, as discharging is then a simple matter. The question of the best number of chambers for high output has been discussed previously. It suffices to say that no great saving

of labour is achieved in the case of long presses, as usually the time lost in attending to the closing gear, letting the press drain, etc., is a fairly insignificant portion of the discharging period. The 20 minutes per operation taken in the mathematical example was a very generous allowance. In most cases not more than 5, or at the most 10, minutes would be necessary, as will be judged from the examples to follow. Recessed plates require distinctly less handling than plates and frames, especially where no washing passages are required. Outside lugs do not make the difference one would expect, except where the cloths are frequently washed. There is also not much to choose among the various closing gears, so long as one is selected which will give efficient pressure. There is distinctly more to be saved by a proper arrangement of the press house, especially if it can be arranged for the operators to proceed directly from closing one press to opening another.

Reasonable room should be allowed all round each press, especially at the side on which the cake is to be brought away. It is helpful to have plenty of space below the press for dumping. Cake trays are distinctly labour economisers, but it is better where practicable to have the presses on an upper floor and discharge through shoots into trucks. Where this is impossible a useful plan is to have the tray or floor made sloping so that the discharged material can easily be raked down into a suitable receptacle. A good arrangement is to have the mixers, auto-claves or dryers which deal with the next operation so grouped with the presses that the discharged cake can be shovelled in direct. The pumps and sludge rams are preferably worked from the same platform as the filter presses, and the mixers which deliver the liquor to them should also be within easy access.

Most of the work depends, however, on the material itself, and the proper building of the cake. If the cake breaks up readily and drops cleanly away from the cloth, labour will be only perhaps one-half of what is necessary if the cake is half formed and sloppy, as then the whole cloth face must be thoroughly scraped. If such a partially built cake is of a clayey nature holding firmly together and binding to the cloth we have the worst conditions of all. Such clayey cakes, if properly built may nevertheless fall away quite readily. Materials containing hard sandy grains require careful attention to the joint surfaces, or these may not come well together. Slimy substances also require more attention in careful cleaning of the cloth faces. If the liquor is such as to make the cloths tender, or if corrosive materials are being handled which might injure the hands of the operators, then again extra care and time are required. Then again, hard wash waters may give a deposit on the plate surfaces when washing out alkali, and labour in cleaning this off may be minimised by a proper attention to the water supply.

Low labour costs also depend on the proper choice of a cloth and the adaptation to filtration of the chemical and physical qualities of the material.

In order to eliminate the varying factors of thickness and weight per cubic foot of the cake it is useful to compare the number of man-hours per operation per 1000 sq. ft. of filter surface.

A 38-in. plate and frame press, with 50 chambers, dealing with tin slimes, took two men $2\frac{1}{2}$ hours to discharge and get ready for restarting, giving a factor of 5.5. In the same establishment a wood plate and frame press, 40 in. \times 45 in. externally, having 50 chambers, treating tungstic oxide, was dealt with by the same gang in $1\frac{1}{2}$ hours, the factor being 4.2. The operation of the closing gear took under 10 minutes. In both cases the presses were of the thorough washing enclosed outlet type, and the cast-iron press did not have outside lugs. In

another works a similar press, but 1 metre square, having outside lugs with rubber joint rings, took about 3 hours to discharge.

In yet another works a 36 in. square press, making thirty 14-in. cakes, with spur wheel and pinion closing, and feed and single wash passage in rim, took 2 men one hour to empty, giving a factor of about 4.2 man-hours. The cakes were dyes of a fairly soft, slimy nature. A press next to it working on the same product was 32 in. square with 40 chambers. It had toggle closing gear and outside ears for feed and wash-ports, and employed practically the same proportion of labour. The times for manipulating the closing gear took 3 minutes and 5 minutes in all for each operation respectively. The whole installation consisted of 6 presses, 3 of each kind, and employed two emptiers, one man shovelling cake from under the press into the mixing vessels, and one operating valves. The work proceeded on the three-shift system, and an additional man was employed during one shift to look after the cloths and keep the plate grooves free. As there were about 30 operations in 24 hours, the factor for the total labour worked out at about 7.15 on the average. In all the above instances unfavourable conditions might increase the time taken by 25% to 50%, while in the case of some dyestuffs the factor may be as large as 11 or 12.

As against this a 38-in. recess plate filter press with 50 chambers would certainly be dealt with in from 30 to 40 minutes all told when working on sewage, giving a factor of 1.48. These figures assume that the sludge is not in the most favourable condition for discharging, nor the labour of the very best.

It is possible to obtain much better results, as, for instance, at the Dalmarnock Works, Glasgow. Through the courtesy of Thomas Melvin, Esq., it may be said that the installation consists of 19 presses, 12 of which have 40 chambers 40 in. square externally, the remainder having 34 chambers. Two labourers discharge from 36 to 37 pressings in an 8-hour shift, averaging one every 13 minutes throughout the day. This gives a factor of about 0.6. A timed operation on one of the shorter units showed that two men took well under 10 minutes, including replacing a cloth, giving a factor of 0.49. The total labour in this instance included in addition a working foreman who operated the valves, one man on the lime mixer and one looking after shoots and wagons. The total labour factor is thus 1.47, and in this instance supervision is included.

In another works, using the very largest type of press, the factor for discharging works out at about 0.91 and the total labour factor 1.36 without including foremen.

It will be seen therefore that the labour required is very dependent on the class of operator and material, much more so than on the size and details of the press itself. This is emphasized by the fact that among the records in the author's possession is one relating to a press with 25 in. square recessed plates, having a number of ports formed in the rim, in which the discharging factor amounted to less than 0.9 when dealing with an intermediate product.

Through the courtesy of Joseph Garfield, Esq., M.Inst.C.E., it is possible to give the following description of the sewer grease recovery plant at Esholt, Bradford. The installation contains 128 presses, making 47 cakes 36 in. square and 12 in. to 2 in. thick. It works continuously day and night, and is operated by compressed air, having an effective pressure of about 80 lb. per sq. in. The sewage is treated with sulphuric acid, causing the solid matter to separate and deposit in settling tanks as sludge. This sludge contains some 80—85% water, and of the remainder some 30—40% is grease. Each filter press is worked for some 71 hours before a complete cake is formed,

sludge being forced in for a couple of hours and then steamed well through for from $\frac{1}{2}$ to $1\frac{1}{2}$ hours according to the amount of cake that has been formed. During the final ten hours the cake is not steamed, as nothing extra is gained. When finished it contains 15–18% of grease and 28–30% of water. Each press holds about 33 cwt. on the average, and this works out at about 78 lb. per cu. ft. The rate of filtration is about 0.06 gall. per sq. ft. per hour. The presses are fitted with pneumatic closing gear and have steam connections to the feed passage at each end of the press. Cotton twill cloths are used, as jute will not stand the steaming, and the life of the cloth is about 6–10 weeks.

About 40–50 presses are discharged per day, and it takes two men an average of about 40 mins. to open, empty and re-close a press, about three cloths being replaced. This gives a factor of 1.79. The total labour is four steamers for each shift, four emptiers, day shift only, and one man on trucks, day shift only. The total factor is, therefore, about 4. This excludes one night and one day supervisor.

In conclusion it may be said that the best success of a filter press installation depends, not only on the choice of plant, but more especially on those in charge of the operations. It is nearly always possible to reduce high labour and cloth charges by proper methods in the lay-out of the plant, and especially in the formation of the precipitate or suspension, and those who take these facts duly to heart will get the most satisfactory results.

The author has to tender his best thanks to the many firms and individuals who have enabled him to collect various data and have given permission to use them for the present purpose. He has in most cases to respect the condition that these should remain anonymous, but he may especially mention Arthur C. Auden, Esq., M.Inst.C.E.; also H. Griffiths, Esq., A.R.C.S., B.Sc., who gave valuable assistance in criticising the proofs. He would also like to thank his wife, who prepared the various microscopic slides etc. for the camera, and carried out some useful researches in regard to filter cloths.

Edinburgh Section.

THE DEPOLARISATION BY OXYGEN OF A VOLTAIC CELL.

BY A. M. WILLIAMS, M.A., D.Sc.

The experiments here described were undertaken at the suggestion of Prof. Henry Briggs, Heriot Watt College, Edinburgh, with a view to obtain an indicator automatically recording the oxygen percentage in the air of mine rescue apparatus and oxygen chambers. The underlying idea was that the polarisation in a voltaic cell due to a film of hydrogen on the positive pole might be removed by a stream of oxygen, and it was sought to establish a relation between the amount of depolarisation and the percentage of oxygen in the current of gas passing over the positive plate.

After some preliminary experiments it was found that a cell in which the gas current passed over a silver gauze separated from a zinc plate by a pad soaked in calcium chloride solution gave a depolarisation relative to air of 0.20 volt with 98% oxygen. The curves obtained on running down through a voltmeter of 167 ohms resistance are shown in fig. 1. It will be noted that in the case of 98% and 65% oxygen there is a large initial drop, the E.M.F. passing through a minimum and then rising to a fairly constant final value.

On taking a second series of observations with a voltmeter of resistance 830 ohms, the final value of

the E.M.F. was much more rapidly attained in the case of the higher percentages of oxygen, there being no minimum such as was noted with the smaller external resistance. It was further found that the depolarisation was proportionately greater with the smaller percentages of oxygen. This is shown in fig. 2. With the 30% oxygen, alternation of air and oxygen caused appreciable movement of the voltmeter needle. There was no refill of the cell during the observations in fig. 2, and hence the cell was apparently capable of giving concordant values for, say, six two-hour runs with rests in

Fig. 1.

between. The rate of flow of gas in these experiments was always about 5–6 litres per minute.

It was noted that pressure on the gauze altered the E.M.F. as registered on the voltmeter—accidental pressure on the cell completely altered the final E.M.F. for several runs. So when a trial cell was specially constructed care was taken that the gauze was tightly stretched and secure from accidental pressure. The introduction of any obstacle in the orifice increased the pressure of the gas in the cell, and since this was equivalent to an increase in the concentration of the oxygen there was an increase in the E.M.F. It was therefore necessary

Fig. 2.

for the orifice to be free from accidental blocking of any kind (and incidentally necessary to correct for any large variation in the barometric pressure).

The effect of diluting the current of gas with carbon dioxide was tested. As a result of several series of observations it was concluded that carbon dioxide acted mainly like the nitrogen in the air—it served simply as a diluent of the oxygen and did not of itself seriously affect the E.M.F. In consequence subsequent observations were confined to oxygen-nitrogen mixtures, save on one occasion when the results with the carbon dioxide merely confirmed the earlier observations.

The above results appeared sufficiently satisfactory to justify the construction of a specimen working cell. It consisted of an ebonite frame across which a piece of silver gauze was stretched tightly. To reduce internal resistance the zinc plate was bent so as to leave a space of only 3 mm. for the pad. The cell fitted into a wooden box through which a current of gas could be blown. The E.M.F. of this cell was 0.830 volt at 20° C., and the internal resistance was 32 ohms. On refilling, the E.M.F. was found to be 0.824 volt and the internal resistance 28 ohms, *i.e.* the condition of the cell was appreciably reproducible.

Observations were taken as before in order to find the value of the E.M.F. with varying percentages of oxygen when the cell was running down through an external resistance of 830 ohms. The resulting curves were of the same type as those shown in fig. 2 and the final values are given in Table I., where $V - V_0$ is the depolarisation. The values under V have been corrected both for internal resistance in the cell and for error in the voltmeter.

TABLE I.

Order of expt.	% oxygen.	V .	$V - V_0$.
2	99	0.75	0.27
4	55	0.645	0.165
5	30	0.53	0.05
1	21	0.48	0.00
3	21	0.48	—
7	21	0.47	—
6	56-21	0.515	—

One series of observations was taken where the percentage of oxygen passing was varied at intervals until 21% was reached. There was a constant 3% of carbon dioxide in the gas in this case, which is represented by the dotted line in fig. 3. The lag is very obvious. In the earlier experiments when air replaced oxygen it will be seen from fig. 2, for example, that the time before the air value was reached varied from 60 mins. with 97% oxygen to 12 mins. with 30% oxygen, and in this case the lag is certainly 20-30 mins.

Fig. 3.

Some experiments were tried with zinc-silver cells containing pads soaked in solutions containing various proportions of zinc chloride and calcium chloride. It was found that the greater the concentration of the zinc chloride the more nearly reversible the cell. Thus with a solution containing 25% of zinc chloride and 25% of calcium chloride the initial E.M.F. was 0.563 volt, falling to 0.550 volt in one minute and after two hours to 0.532 volt. The effect of a current of oxygen on such a cell was to increase the E.M.F. by 0.037 volt—comparable with the effect with an earlier carbon-zinc cell.

Other experiments were directed to finding how the depolarisation varied with different metals,

using the solution employed with the typical silver gauze cell. The internal resistances varied somewhat as the cells were roughly constructed. The following table gives some of the results.

TABLE II.

Gauze.	Registered depolarisation.	Actual depolarisation.
Silver	0.22	0.275
Copper	0.11	0.14
Nickel	0.18	0.33
.. .. .	0.145	0.21

The nickel cell resistance was greatest owing to the difficulty in wetting the gauze. When the gauze was more efficiently wetted the depolarisation fell, pointing to the fact that thorough wetting tended to render less easy the access of the oxygen to the electrode.

The experiments so far described were all performed at room temperatures. It was now sought to find the influence of temperature on the standard type and a set of observations was taken at 40° C. The change in the initial E.M.F. with temperature was small, being from 0.83 volt at 15° C. to 0.82 volt at 40° C. when in air. To eliminate troubles due to drying of the pad it was found necessary to pass the air and oxygen currents over a surface of water heated to a temperature a little below that of the cell. The depolarisation registered was much the same as at 15° C., but there was this difference—the cell ran down much quicker at the higher temperature and refills were more frequent. Equilibrium when air replaced oxygen was attained in about 20 mins., which was much more rapid than with the corresponding observations at room temperatures.

A set of observations was also taken at 40° C. with two small cells in series. These were constructed according to specification and were about 2.5 cm. x 3.8 cm. each. The initial E.M.F. was over 1.70 volt and the registered E.M.F. fell from more than 1.00 volt to 0.46 volt in 1 min., and to 0.285 volt after 2 hrs. in a stream of air. With an oxygen current the E.M.F. fell to a steady value of 0.70 volt in 40 mins., and on replacing oxygen by air after a further 40 mins. the value fell from 0.695 to 0.350 in 1 min. and attained the equilibrium value of 0.285 volt in 20 mins. The registered depolarisation was thus 0.41 volt, while the actual depolarisation was 0.50 volt.

Summary and conclusions.

1. The depolarisation of a voltaic cell by a stream of oxygen passing over the positive plate may amount to 0.3 volt, which is much greater than can be accounted for by a simple gas-concentration effect.
2. The depolarisation is greater the less wet the gauze constituting the positive plate.
3. With a low resistance the polarisation takes place more quickly than the depolarisation, though this eventually overtakes and reduces the polarisation.
4. The less run down the cell the more sensitive it is to depolarisation by the oxygen.
5. The more nearly the cell approaches reversibility, the more closely does the depolarisation by the oxygen approach a gas-concentration effect.
6. Polarisation and depolarisation take place more rapidly at higher temperatures.

In conclusion the author desires to thank Professor James Walker, F.R.S., for his kindness in providing facilities for the prosecution of this research in the Chemical Laboratory, University of Edinburgh.

Communications.

THE ACCELERATION OF VULCANISATION. PART II.

A Discontinuity in the Effect of Vulcanisation.

BY D. F. TWISS AND C. W. H. HOWSON.

In the previous paper on the above subject (J., 1920, 125 τ) the results were given of comparative experiments with aldehyde-ammonia, *m*- and *p*-phenylenediamine, thiocarbanilide, and hexamethylenetetramine.

The present paper contains the results of further tests. The method of procedure was the same as that adopted earlier, the most important feature being the use of a heated bath of oil for vulcanisation of the samples, whereby the periods of vulcanisation are rendered more definite than with steam heating.

Fig. 1 represents the progress of vulcanisation of the standard mixing (pale cr pe rubber 90, sulphur 10) with and without the addition of 1% and 0.4%.

A, 1% MgO; B, 0.4% MgO; C blank (S=10%).

Fig. 1.

of a high-grade, light calcined magnesia. Judging the rate of vulcanisation by the period required for the attainment of maximum tensile strength, the acceleration factor (*loc. cit.* p. 129 τ) for the magnesium oxide in question is approximately 3.3 and 2.5 respectively for 1% and 0.4%; the presence of the finely dispersed particles of undissolved magnesium oxide somewhat affects the extensibility of the rubber, and the acceleration factor assessed by the periods required for the reduction of the extensibility at 0.5 kg. per sq. mm. to 650% possesses a slightly exalted value.

In fig. 2 is represented the effectiveness of 0.5% of potassium hydroxide introduced as a solution in three times its weight of glycerol (see Twiss, J., 1917, 1185). The acceleration factor judged by the tensile strength method or by the period for the production of extensibility of 650%, has a value between 3 and 4, which compares very favourably with many popular organic accelerators at the same concentration and is approximately equal to the factor for the magnesia in the preceding experiment at twice the concentration.

The insistence of supporters of the use of thiocarbanilide that this substance needs the simultaneous presence of zinc oxide for the development of its catalytic effect, was suggestive of the possibility that the active substance might really be carbodiphenylimide, $C(NC_6H_5)_2$, produced from the thiocarbanilide, $CS(NH.C_6H_5)_2$, by the desulphurising effect of the zinc oxide, and which is known to be remarkably active chemically. An ex-

periment made with a sample of carbodiphenylimide prepared by the action of mercuric oxide on thiocarbanilide in benzene solution revealed no marked catalytic activity, but on account of the easy polymerisation of carbodiphenylimide this evidence could not be regarded as final, and it was considered necessary to produce the carbodiphenylimide *in situ* by the interaction of the thiocarbanilide and mercuric oxide in the rubber mixing. Parallel vulcanisation experiments were therefore made using (a) the standard mixing of rubber 90, sulphur 10; (b) the standard mixing with the addition of 1% of thiocarbanilide and 3% of yellow mercuric oxide; and (c) the same mixture as in (b) but without the thiocarbanilide. The results given in fig. 3 show that mixture (b) possesses no marked advantage in rate of vulcanisation relative to (c), and that any advantage in rate of vulcanisation imparted to a mixing by the introduction of thiocarbanilide cannot be ascribed to the formation of carbodiphenylimide. It is noteworthy, however, that

Fig. 2.

the curves for mixing (c) indicate marked catalytic power on the part of the mercuric oxide, which, indeed, might have been expected from the basic character of this substance.

Reference to fig. 12 in the previous paper (*loc. cit.*, p. 131 τ) reveals the remarkable fact that, although the mixing containing the organic catalyst together with zinc oxide, vulcanises much more rapidly than the blank mixing, the slope of the extensibility or elongation curve in the lower part of the diagrams, instead of being steeper, tends to be more gradual. Closer examination of the behaviour of mixtures of this composition reveals the fact that the extensibility curve in question undergoes a remarkable change of direction at an early stage of the vulcanisation process. A similar phenomenon is observable with a rubber-sulphur mixing containing as accelerator a mixture of triphenylguanidine and zinc oxide. The results are reproduced in figs. 4 and 5. In both cases the extensibility at first decreases very rapidly with increasing vulcanisation, but finally assumes a much more gradual rate of change.

The presence of zinc oxide appears to be favourable, if not conditional, to the occurrence of the

inflexion in the extensibility curve within the usual range of vulcanisation. From the results given in the previous paper it is evident that no indication of such inflexion exists in the extensibility curves

the bend appears to be absent the extensibility curve undergoes a change of direction at a stage of vulcanisation beyond the range of convenient testing.

Fig. 3.

Fig. 4.

Fig. 5.

for the mixings containing aldehyde-ammonia; when the aldehyde-ammonia is used in conjunction with zinc oxide, however, an inflected extensibility

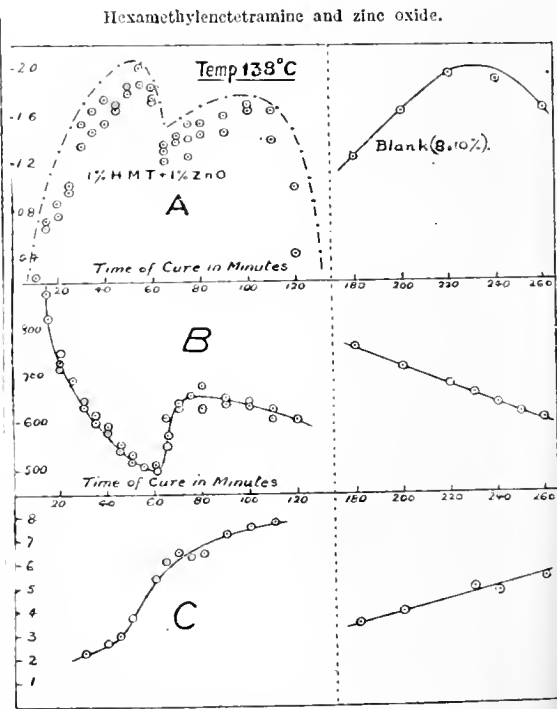

Fig. 6.

curve is obtained, as is demonstrated by the results in fig. 6. No such inflexion appears to occur in the progressive vulcanisation of the standard rubber-sulphur mixing with the addition of thiocarbamide and zinc oxide. It is possible, however, that when

Curves show rates of cure as indicated by (A) tensile strength, (B) elongation, (C) vulcanisation coefficient.

Fig. 7.

By concentrating the number of tests around the point of inflexion of the extensibility curve for the hexamethylenetetramine-zinc oxide mixing it is found that, in at least this case, the curve in reality undergoes a double inflexion within a short in-

terval of time (figs. 7 and 8).^{*} This surprising result has been confirmed by repeated re-investigation with different mixings of the same composition vulcanised at the same and different temperatures. The results also indicate some concomitant discontinuity in the tensile strength and combined sulphur curves, but the actual outline of the tensile strength curves in figs. 7 and 8 is given with a certain amount of reserve on account of the somewhat greater variability in the values obtainable. It is noteworthy that the inflexion in the extensibility curve occurs at a vulcanisation coefficient of 4–5, indicating that the first peak in the tensile strength curve represents the ordinary "optimum cure," and that the subsequent peak is the abnormal one; it may also be observed that the maximum extensibility attained just after the inflexion of the curve, has approximately the value of 650 commonly observed at the tensile optimum of a rubber-sulphur mixing vulcanised under ordinary

Hexamethylenetetramine and zinc oxide.

Curves show rates of cure as indicated by (A) tensile strength, (B) elongation.

Fig. 8.

conditions. The explanation of this unexpected irregularity in the alteration in the physical characteristics of the rubber is not at all obvious; it appears probable that the two sections of the extensibility curve indicate two distinct processes causing alteration in the physical characteristics of the rubber, the point of inflexion representing the stage at which the one preponderating earlier is overtaken by the other, which then becomes predominant.

From the curve in fig. 7 it will be seen that for one mixing it may be possible within a small range of cure to apply three distinct periods of vulcanisation and yet to obtain identical extensibility in the resulting rubber in spite of the three different vulcanisation coefficients. Such a result, which is independent of the further complications introduced into the relation between the physical properties and the vulcanisation coefficient by subsequent "ageing" (see Reports of the Progress of Applied

Chemistry, 1919, 4, 338), serves to emphasize more strongly than ever the lack of simplicity in the relationship between the physical alteration effected in rubber during vulcanisation and the chemical change by which this alteration is induced.

Grateful acknowledgment must again be made of the permission of Mr. J. V. Worthington, Technical Superintendent and Director of the Dunlop Rubber Co., for the publication of the foregoing results.

NOTE ON A PAPUAN NATURAL PETROLEUM. PART II.

BY PROF. J. READ, M.A., PH.D., AND MISS A. C. P. ANDREWS, B.Sc.

In a previous communication from this laboratory some of the characteristics of a hitherto undescribed natural petroleum, from Papua, were recorded (J., 1919, 319 t). The results demonstrated that a "170° run" of the Papuan oil contained about 11% of aromatic hydrocarbons, from which a fraction having a combined content of benzene and toluene amounting to about 10% could readily be obtained. The Papuan oil thus contains appreciable amounts of aromatic hydrocarbons, although it is less rich in these than Borneo petroleum (*cf.* Jones and Wootton, Chem. Soc. Trans., 1907, 91, 1146). The observations now recorded deal largely with the higher boiling fractions, and were made upon material obtained from the second sample of Papuan petroleum (No. 5 bore, Government Oil-field, Upoia, Papua) mentioned in the foregoing paper.

Crude oil.

The crude oil had sp. gr. 0.7965 at 22° C., and $n_D^{20} = 1.4489$.

"180° Run."

When the crude oil was distilled up to 180° C. from an ordinary flask the fraction passing over ("180° run") amounted to 44.65%, by weight, of the original material. It had sp. gr. 0.755 at 22.25°, $n_D^{20} = 1.425$. When distilled (*loc. cit.*) through a column, the "180° run" yielded the fractions numbered 1 to 4 in Table A below.

Residuals boiling above 180°.

The reddish-brown fluorescent residue left in the distilling flask after the preceding distillation amounted to 55.35%, by weight, of the crude oil, and had sp. gr. 0.831 at 25° C.; $n_D^{20} = 1.4615$. The total amount utilised in the work described below was about 1800 grams.

Upon heating this residue in an ordinary distilling flask, distillation began at 90° C., and a small fraction had collected at 180°. The first fraction was cut at 220° and second and third fractions were collected up to 260° and 300° respectively (see fractions 5, 6, and 7, in Table A). In each fraction a cloudiness was observed, followed by the separation of a small heavy layer of liquid. This layer became semi-solid in the last fraction. In all three cases the fraction became homogeneous when shaken and allowed to stand. The first of these fractions, which was very similar in appearance and odour to good kerosene, was colourless, the second faintly yellow, and the third pale yellow. Slight fuming was noticeable as the temperature approached 300° C., but there was no rank odour indicative of "cracking." At 235° a white semi-solid deposit was formed on the sides of the condenser-tube. The temperature remained constant for some time at 251° and at 269° C. The specific gravities and refractive indices (see Table A) show a gradual increase with rising boiling point.

By interrupting the distillation at 210° and allowing the residue to cool, a dark-brown gelatinous mass was obtained. The residue left after distilling to 300° set to a semi-solid cake when cold; the

^{*} The effect, which is observable over only a small range of concentration, is probably to be attributed to the physical nature of the zinc oxide as an exceedingly fine powder rather than to its chemical nature; 1% of carbon black (gas black or lampblack) introduces a similar irregularity.

amount of this residue corresponded to 16.6%, by weight, of the original petroleum.

Residuals boiling above 300°.

The bulk of the residuals boiling above 300° was distilled under reduced pressure, but in one instance the distillation was carried to 350° under atmospheric pressure. Towards the end of this process the distillate solidified in the condenser-tube. Fractions collected between the limits 300°—340° and 340°—350° amounted to 6.2% and 2.2%, respectively, calculated on the weight of the original crude oil, and the residue represented 8.2% of the crude oil.

The main residues boiling above 300° were distilled from a Claisen flask under a pressure of 18 mm. in portions of about 60 g., the temperature of distillation being carried to 255° by means of a metal bath. The four portions noted in Table A (Nos. 8, 9, 10, and 11) were thus collected. From about 225° the distillate partially solidified to a brownish-yellow waxy mass as soon as it reached the receiver, and at a higher temperature partial solidification occurred in the condenser-tube. Each fraction had a darker yellow colour than the one preceding. The last two fractions (Nos. 10 and 11) exhibited a crystalline formation interspersed throughout a viscous liquid. The first of these fractions, when warmed, became completely liquid at about 20°, but in the other case (No. 11) the material remained partly solid at 35°, and the specific gravity was therefore observed at 40°. The dark-brown solid mass remaining in the Claisen flask corresponded to 5.9% of the original oil.

Residuals boiling above 255° at 18 mm.

The solid dark-brown residue just referred to possessed a greasy feel and was almost odourless. It was not appreciably decolorised by treatment with animal charcoal. Attempts to obtain pure crystalline material from it by slow deposition from solvents and by volatilisation were unsuccessful. A portion of the residue was again distilled under reduced pressure, and in this way further fractions containing crystalline material were obtained (Nos. 12, 13, and 14). Fraction 12, when liquefied, exhibited a pronounced brown fluorescence, whilst with fraction 13 the fluorescence was green. The final residue, which failed to distil below 310° at 20 mm., was quite hard; it was black, somewhat sticky, and practically odourless. The amount was 0.9% of the crude oil.

Summary of fractions obtained.

The appended table indicates the character and yield of the various fractions into which the crude oil was resolved:—

TABLE A.
Fractional distillation of Papuan petroleum.

Fraction no.	B.p., °C.	Pressure.	Weight percent- age of crude oil.	Sp. gr.	Refractive index, n_D^{20}

† Not redistilled.

* After removing crystals.

None of these fractions up to No. 8 exhibited any measurable optical rotation when examined in a 2 dm. tube at 20° C. in sodium light. Fraction 9, however, under these conditions gave a dextro-rotation of 0.05°; whilst fraction 10 gave $\alpha_D = +0.10^\circ$ in a 2 dm. tube. Fraction 11 was too dark to read accurately, even in a 1 dm. tube, but it appeared to possess a small dextro-rotation. The above values are of the same numerical order as those recorded by Kakuzin for Russian and American petroleum, both of these groups being also as a rule dextro-rotatory (J. Russ. Phys. Chem. Soc., 1904, 36, 554). Jones and Wootton (*loc. cit.*) also observed similar values for Borneo petroleum, but in this case the rotation was to the left.

Isolation of normal tricosane.

The crystalline material present in fraction 10 (b.p. 200°–225° at 18 mm.) was separated from the accompanying viscous liquid by filtration with suction and dried by pressure on a porous plate. The almost colourless crystals so obtained were readily soluble in light petroleum or in ether, but were only sparingly soluble in cold alcohol. When purified by crystallisation from hot alcohol the product consisted of colourless leaflets melting at 48° (corr.). The melting point was unaltered by recrystallisation. The original thick oily filtrate slowly deposited further quantities of similar crystalline material upon standing in the cold.

The substance, in benzene solution, showed no pronounced reaction with bromine and upon combustion it yielded C=85.0% and H=14.9%. It was therefore identified as normal tricosane, $C_{23}H_{48}$ (m.p. 48°; b.p. 234° at 15 mm.; C=85.1%, H=14.9%), a hydrocarbon which hitherto has been identified in brown coal paraffin and in Pennsylvania petroleum.

Fraction 11 (b.p. 225°–255° at 18 mm.) yielded a further quantity of the same hydrocarbon, but the total weight obtained from the whole of the distillates amounted only to a few grams.

Upon concentrating the alcoholic mother liquors from the purified tricosane a crystalline deposit melting at 40°–42° was formed. It seems probable that this contained heneicosane, $C_{21}H_{44}$ (m.p. 40.4°; b.p. 215° at 15 mm.).

Isolation of normal pentacosane and normal heptacosane.

By treating fraction 12 (b.p. 255°–275° at 20 mm.) in the manner just outlined, and recrystallising the solid product three times from hot alcohol, colourless leaflets were obtained of m.p. 54.3°–54.8° (corr.). The substance was similar to tricosane in appearance and properties, and upon combustion it gave C=85.0% and H=14.8%. It was accordingly diagnosed as normal pentacosane, $C_{25}H_{52}$ (C=85.1%, H=14.9%). This hydrocarbon does not appear to be well known; Mabery, who isolated it from Pennsylvania petroleum, recorded the melting-point as 53°–54° (Amer. Chem. J., 1902, 28, 193); and Marie, who prepared it from cerotic acid, gave the melting point as 54° (Ann. Chim. et Phys., 1896 [7], 7, 214).

From fraction 13 (b.p. 275°–305° at 20 mm.) was isolated in a precisely analogous manner a colourless crystalline substance possessing similar properties and melting at 60.5°–60.8° (corr.). Upon combustion this yielded C=85.0%, and H=14.8%; it was thus recognised as normal heptacosane, $C_{27}H_{56}$ (m.p. 59.5°, or 60°; b.p. 270° at 15 mm.; C=85.2%, H=14.8%). This hydrocarbon has been recorded as a constituent of beeswax, tobacco, and soot (Meyer and Jacobsen, Lehrbuch d. org. Chem., 1907, I, i, 164).

The weight of each of these hydrocarbons isolated amounted only to a few grams. The final residues probably contain still higher members of the paraffin series. The highest paraffin hydrocarbon reported by Mabery (*loc. cit.*) in Pennsylvania petroleum is $C_{28}H_{58}$; but the next three members

have been found in various eucalyptus and other natural essential oils (*cf.* Smith, J. Proc. Roy. Soc. N.S. Wales, 1913, 47, 95).

None of the three hydrocarbons described above exhibited optical activity when dissolved to a 7% solution in light petroleum and examined in a 2 dm. tube in sodium light.

The weak optical activity of Papuan petroleum suggests an organic origin for this material. It is thus particularly interesting that each of the three (or four) high paraffin hydrocarbons yet isolated from it possesses an odd number of carbon atoms in the molecule, so that they stand in close chemical relationship to such typical products of organic activity as bebenic, cerotic, melissic, and other high fatty acids with an even number of carbon atoms in the molecule. In the case of Pennsylvania petroleum, however, Mabery (*loc. cit.*) isolated an almost unbroken series of paraffin hydrocarbons from $C_{11}H_{22}$ to $C_{25}H_{50}$; a more detailed examination of the paraffins occurring in Papuan petroleum would therefore be of considerable interest when larger amounts of the material become available for distillation.

Main characteristics of Papuan petroleum.

Among the leading features of this petroleum are absence of pronounced colour or odour in the original oil and in the various fractions; absence of sulphur and nitrogen; and low original specific gravity. Connected with the last feature are the unusually high yield of low-boiling distillates and the small proportion of high-boiling residuals afforded by the oil, the "benzine" fraction (to 150°) amounting to 36%, and the "kerosene" fraction (150°–300°) to 46%, by weight, of the crude oil.

Corresponding data for other natural petroleum are listed in the following table (Meyer and Jacobson, *loc. cit.*, 187; Jones and Wootton, *loc. cit.*):—

TABLE B.

Fractional distillation of various natural petroleum.

Locality.	Sp. gr. of crude oil.	"Benzine," to 150° (°).	"Kerosene," 150–300° (°).	Residues, above 300° (°).
Pennsylvania	0.79–0.82	10–20	55–75	10–20
Caucasus	0.85–0.90	5	25–30	60–65
Gallia	0.82–0.90	5–30	35–40	30–55
Ohio	0.80–0.85	10–20	30–40	35–50
Borneo	0.83–0.87	19	51	27
Papua	0.796	36	46	17

In the case of Borneo petroleum it is stated that no distillate passes over below 100°, whereas the Papuan product yields 5% of distillate up to 90°, but there is a decided similarity between these two petroleum. The total amount of aromatic hydrocarbons present has not been determined, but the crude oil contains about 4% of such hydrocarbons distilling below 170° C. (*i.e.*, benzene, toluene, xylenes, etc.). Chemically, Papuan petroleum consists largely of paraffin hydrocarbons, not only with aromatic hydrocarbons, but also with other cyclic hydrocarbons, as is indicated by the high physical constants exhibited by the residues from nitration processes (*cf.* table C.).

Similar considerations hold for the fractions of higher boiling point. For example, the fraction distilling at 220°–260° has sp. gr. 0.820, whilst the value for the corresponding paraffin hydrocarbon is about 0.775. Again, tricosane, with sp. gr. 0.778, occurs in a fraction having sp. gr.

over 0.86. In these cases, as in the others quoted, there is no evidence of the presence of open-chain hydrocarbons other than paraffins, and the high

TABLE C.

Physical constants of original fractions and of residual hydrocarbons after nitration.

Fraction.	Specific gravity.		Refractive index, n_D^{20}	
	Original fraction.	Residual hydrocarbons	Original fraction.	Residual hydrocarbons
60°–90°	0.715 / 24°	0.710 19.5°	1.4088	1.3994
90°–120°	0.744 / 21.5°	0.747 17°	1.4161	1.4090
120°–150°	0.7615 / 25°	0.768 19.5°	1.4278	1.4160

specific gravity and refractive index must therefore be ascribed to the presence of aromatic hydrocarbons, possibly in association with other types of cyclic hydrocarbons. Although much work remains to be done upon these constituents of the oil, the main character and potentialities of this interesting natural product may be gauged from the data now rendered available.

THE CONSISTENCY OF GREASES.

BY F. S. CLULOW, B.SC., A.R.C.S., A.I.C., AND C. W. TAYLOR, A.R.C.S., A.I.C.

In the course of experiments on the viscosity of lubricating greases it was found that the results obtained with present-day apparatus were of little practical value for comparing the behaviour of greases under actual working conditions. For example, a stiff grease used for lubricating a piece of mechanism such as a gear box has its consistency considerably reduced after working, although the temperature remains practically constant. This led to the realisation that the viscosity or consistency of a grease at a given temperature was not a definite physical property, as in the case of an oil, but seemed to depend on certain other conditions. Results obtained from experiments with a Küssing penetrometer appeared to support this view. The grease under examination was melted and poured into a large crystallising dish, where it was allowed to cool. When cooled and tested with the penetrometer it was found that the consistency at the centre was greater than that near the edges (except very near the edge, where the close proximity of the side of the vessel affected the result). The only explanation of this seemed to be that the rate of cooling affected the result, as the centre portion would have cooled more slowly than the edges.

Experiments were carried out with the Küssing viscometer, but the results obtained were unsatisfactory. In order to obtain anything like concordant results the same tube has to be used, as the friction of the piston varies with the different tubes, and this entails waiting a day between each experiment. The chief disadvantage of the apparatus, however, is that it affords no means of examining the viscosity under different conditions, except that of temperature, and subsequent work showed that it indicated a higher viscosity than the grease possessed under actual working conditions.

In order thoroughly to investigate the problem an attempt was made to measure any change of viscosity due to mechanical treatment or the rate at which the grease had been previously allowed to cool after melting. The apparatus used for the purpose consisted of two elongated bulbs about 3 cm. diam. and 10 cm. long, connected by a

tube 3 cm. long and 3 mm. internal diameter, enclosed in a constant temperature bath. The time required for the lower surface of the grease to rise between two marks in the lower bulb, at a given temperature and under a known head of mercury from a reservoir attached to the lower bulb, was observed. The apparatus gave a series of useful results, but had one or two defects, the chief being a tendency for the mercury to push through the centre of the grease occasionally, thus forcing a thin core of grease above the surface at the top. This, of course, diminished the volume of grease forced through the capillary. In order to overcome this difficulty a new apparatus was devised in which both surfaces of the grease were in contact with mercury. Also, arrangement was made to give a constant head of mercury throughout the experiment.

The apparatus consists of an inverted U-tube, 4 mm. int. diam., having a cylindrical bulb on each limb 10 cm. long and 14 mm. diam., the narrow tube connecting the two being fitted with a branch tube and tap for filling purposes. The free ends of the limbs are connected by means of pressure tubing to movable mercury reservoirs, 14 mm. diameter, which reservoirs are connected by a gut string passing over small pulleys, so that when one reservoir moves up the other moves down an equal amount. This amount of movement is measured by means of a millimetre scale behind them. By altering the length of the gut, the head of mercury can be varied at will. A jacketing apparatus is provided to keep the U-tube and bulbs at constant temperature.

The method of procedure is as follows:—The temperature of the water jacket is raised to a few degrees above the melting point of the grease. By raising both reservoirs, with the tap open, the tube is completely filled with mercury. The melted grease is poured in through the tap, the reservoirs being slowly lowered until the mercury in both bulbs is at the zero mark. The tap is turned off and the grease allowed to cool to the temperature at which the experiment is to be conducted. The right-hand reservoir is then brought to the zero mark and the gut adjusted so that the mercury surface in the left-hand reservoir is 140 mm. below this level. This is the head of mercury used throughout the succeeding experiments with this apparatus. As the mercury level in the right limb moves up, forcing the grease through the tube, the right reservoir is slowly raised, keeping the mercury surfaces level. By means of the gut string an equal downward movement is communicated to the left reservoir,

thus maintaining a constant pressure. The time noted is that required for the mercury surface to move 20 mm. above and below the zero in either limb.

When a grease is freshly solidified, the pressure of 140 mm. is occasionally insufficient to cause movement, in which case it may be set in motion by constricting the pressure tubing of the right limb, after which the normal pressure is sufficient.

Standardisation of apparatus.

As one apparatus will differ slightly from another in dimensions, it is necessary to standardise each apparatus. Castor oil was found to be suitable for this purpose if tested at about 0° C. The pure oil employed had sp. gr. 0.96345 at 21° C., and absolute viscosity 8.4586 at 21° C. The head of mercury, as stated before, was 140 mm., and the experiment was conducted at temperatures between -2° C. and 4° C. A direct determination at 0° C. was found to agree with that obtained from the time-temperature curve.

Appended are the results:—

Temp. ° C.	Time of flow, secs.	Temp. ° C.	Time of flow, secs.
-1.2	16.2 16.0	0	13.5
-1	16.1	+1.5	12.0
-0.5	15.5	+0.5	13.0
	14.0 14.2		
-0.2	14.4	+1.7	11.7
	13.8 13.7	+4.5	9.1

It is proposed that each apparatus should be standardised by using such a head of mercury as will produce a time value of 13.5 seconds for castor oil at 0° C. By this means the results obtained with different pieces of this apparatus will be rendered comparable.

The first grease to be examined was a sample of American anti-foaming grease, and it was tested in the first form of apparatus. Having filled the tube, the temperature was adjusted at 32° C., and after allowing half an hour for the grease to reach this temperature, the experiment was commenced. It was found that each successive time the grease was forced through the tube the rate of flow increased, although the temperature was kept constant throughout. After working the grease up and down many times, a constant time was at last obtained which could not be decreased by further working. Another sample of the same grease was similarly tested and was found to give the same minimum value.

The following are the time values obtained at 32° C.

Time of flow in seconds:—720, 345, 304, 259, 185, 155, 140, 135, 125, 127, 115, 113, 98, 92, 85, 84, 83, 81, 76, 60, 56, 48, 37, 35, 33, 35, 32, 31, 26, 28, 28, 24, 23, 21, 20, 20, 19, 18, 19, 17, 16, 17, 15, 15, 15, 15, 15, 15.

It was found that the viscosity only increased very slightly when the worked grease was allowed to remain for 90 hours at about the same temperature and then again tested at 32° C., rapidly dropping to the same minimum value on working, as the following figures show:—

Time of flow in seconds:—45, 20, 17, 16, 16, 16, 15, 15, 15, 15, 15.

The worked sample of grease was then re-melted in the tube by heating the water jacket. It was allowed to cool to the original temperature of 32° C. when it was found to have regained its high initial viscosity, which gradually dropped to the same minimum value after working.

The method of experiment was then varied. The temperature was gradually increased or decreased a degree or two at a time, and the time of flow at

each temperature taken, allowance being made for the grease to attain that temperature. After repeating this several times, it was found that a constant value was again obtained for each tem-

the grease only regained its original high viscosity on re-melting and cooling, led to the theory that the grease was originally crystalline, the crystalline structure being broken up on working.

perature, which represented the minimum viscosity at that temperature. On plotting the temperature against corresponding time values, with the temperature rising and falling alternately to its highest and lowest limits, a series of oscillating curves were obtained, which gradually became closer and finally coincident. This final curve represented the minimum viscosity of the grease. The following results obtained for "vaseline" (sp. gr. 0.8762 at 21° C.) illustrate this:—

Rising temperature.

Temp., ° C.	Time of flow, seconds.

To examine this theory, photo-micrographs of the anti-foaming grease were taken between crossed Nicols under differing conditions. The results obtained proved this assumption to be correct.

A film of greaso was also melted between two cover slips which were placed on mercury to get almost instantaneous cooling. Only a slight trace of crystalline structure was observed.

After further working of the same sample the crystalline structure had entirely disappeared. This represents the condition of the grease at its minimum viscosity, and explains why the value is always the same for the same grease at the same temperature.

Slides prepared for "vaseline" exhibited a similar crystalline structure.

In order to demonstrate that the slowly cooled grease actually has a higher initial viscosity than

The foregoing results indicate the lowering of viscosity by mere mechanical treatment, which points to an alteration in the structure of the grease. This, in combination with the fact that

a more rapidly cooled one, and also has its viscosity reduced more slowly on working, the following experiments were carried out.

(1.) The viscometer was filled with melted "vaseline," the water jacket allowed to cool as

slowly as possible, and a series of viscosity tests performed at 14° C. The results are shown in Curve 1.

(2.) The viscometer was filled with melted "vaseline," and the water jacket cooled as rapidly

1. Grease melted on the slide and allowed to cool exceedingly slowly (about 1 day). $\times 126$.

3. Grease cooled quickly by placing slide on a stone slab. $\times 126$.

2. Melted grease allowed to cool in 1 hour. $\times 126$.

4. Slowly cooled grease after being mechanically worked for some time. $\times 126$.

Curves showing reduction in consistency of (1) slowly and (2) quickly cooled vaseline. Temp. 14° C.

Wool fat. Sp. gr. $21^{\circ}/4^{\circ}$ 0.9397.

as possible, and a series of viscosity tests performed at 14° C. The results are shown in Curve 2.

The curves show that the initial viscosity of 1 was higher than that of 2, and in the case of 2 the viscosity was more rapidly diminished on working, as was expected. If it had been practicable to obtain a greater difference in the rates of cooling of the two samples, the curves would no doubt have shown still greater divergence.

Slides were prepared of various greases tested in the viscometer. Their behaviour in each case was such as would be expected from their appearance under the microscope.

A sample of wool fat photographed between crossed Nicols showed no crystalline structure, being completely isotropic. It was therefore expected that the viscosity would not alter on working. This was found to be the case. No matter for how long the grease was worked, the viscosity for each temperature was always the same.

Coconut oil $\times 25$.

The crystals of palm oil are of a feathery type, which appear as if they would be easily broken up on working. It was, therefore, expected that the viscosity would drop rapidly at first and then rapidly reach the minimum. This was actually the case as shown by the curve.

Coconut oil, as seen from the photograph, crystallises very distinctly, the temperature of crystallisation being about 18.2° C. The grease was very difficult to work below this temperature in the viscometer.

It was found easier to start at the highest temperature and work down to the lowest, owing to

sudden crystallisation at the lower temperatures, so the curves are all drawn from tests with a falling temperature.

Palm oil $\times 25$.

The foregoing results show that for the measurement of viscosity to be of practical value it is necessary to state under what conditions the viscosity was determined, and these should resemble as nearly as possible the conditions under which the grease is to be utilised. It is obviously useless to quote the viscosity at a certain figure when, after a few minutes' working in a piece of machinery, it diminishes to a fraction of that amount. In this case the minimum viscosity, as determined by the apparatus described, is the only one which is of any practical value, as it is independent of all factors which tend to produce varying results with other empirical forms of apparatus.

The results obtained with the improved form of viscometer may be expressed as time values or as the ratio of the time value for the grease under examination, to that for castor oil at 0° C. If this latter method be adopted, a measure of the absolute viscosity of the grease may be obtained by knowing the absolute viscosity of castor oil at 0° C., since the ratio of the time for castor oil at 0° C. to the time for the grease at t° C. is equal to that of the absolute viscosity of castor oil at 0° C. to the absolute viscosity of the grease at t° C.

THE DISTILLATION OF CAMPHOR IN INDIA.

BY JOHN LIONEL SIMONSEN AND TARAK PRASAD GHOSE.

The object of this paper is to record the results of experiments which have been in progress at Dehra Dun for some years past on the camphor content of the various portions of the *Cinnamomum camphora* grown at Dehra Dun and elsewhere within the Indian Empire.

As a general rule camphor wood is the main source from which the camphor and camphor oil are distilled, but in view of the length of time required for the growth of the trees, these experiments have been mainly concerned with determining whether the leaves from coppiced trees could not be utilised. For purposes of comparison twigs have also been distilled and the whole of two trees.

The distillations have been performed on a "semi-large scale," from 30 to 40 lb. of leaves being distilled at one time in a specially designed still (see Puran Singh, Chem. Eng., 1915, 45, 185), having double surface condensers which enable a portion of the camphor to be condensed directly and the oil to be collected separately.

The results of the experiments are tabulated in Tables 1, 2, and 3, the yields being calculated on the dry leaves, twigs, or wood.

TABLE I.
Distillation of leaves.

1919	—	0.19	0.3	0.61

The yield of camphor and of camphor oil is thus satisfactory and compares not unfavourably with the yield obtained elsewhere (cf. Parry, "Essential Oils," p. 151).

The leaf oil, from which 38% of camphor had been separated, was carefully investigated and was found to contain *d*- α -pinene, dipentene, cineol, terpineol, caryophyllene, and a trace of cadinene. Safrol, which is present in camphor wood oil, was

absent. The presence of caryophyllene in camphor oils has not, so far as the authors are aware, been previously observed. In the oil examined it was the principal sesquiterpene present; bisabolene could not be detected and cadinene only by means of its colour reactions. Sufficient of the sesquiterpene fraction was not available for so detailed an investigation as was made by Semmler and Rosenberg (Ber., 1913, 46, 768).

Stem	nil	0.95	0.95
Roots	nil	2.03	2.03

The oil from the twigs resembled that from the leaves, except for the absence of cineol. It contained much less camphor in solution, but this is a matter of little importance, since in any case the yield of oil from the twigs is too small to warrant their commercial distillation.

The wood oil from Indian camphor trees is similar, though apparently simpler in constitution to that from other places. It contains safrol in considerable quantity, but cineol is absent. The sesquiterpene fraction contained caryophyllene and cadinene. A considerable proportion of a high boiling fraction was isolated which was possibly identical with Semmler and Rosenberg's camphoracene. Sufficient was not, however, obtained for investigation.

It thus appears probable that the distillation of camphor and of camphor oil from the leaves of coppiced trees of the *Cinnamomum camphora* could be profitably undertaken, but before a definite opinion can be expressed it must be determined how frequently the leaves can be plucked and the annual acreage yield. Experiments in this direction are in progress.

Experimental.†

Camphor leaf oil.—The oil available for these experiments was pale yellow, and on cooling in a freezing mixture did not deposit any appreciable quantity of camphor. It had sp. gr. 30°/30° 0.9165, $n_D^{30}=1.47$, $[\alpha]_D^{30}=+32.74$. After washing with dilute alkali to remove any acids and phenols,* the oil was carefully fractionated at the ordinary pressure (705 mm.), using a four-pear Young still-head, when the following fractions were obtained: 150°—190° (sp. gr. 0.8795, $n_D=1.463$, $[\alpha]_D=+25.55$) 41.7%; 190°—212° 39%; residue boiling above 212° 19.3%. The second fraction, which was semi-solid,

† All specific gravities were taken at 30°/30° C. and refractive indices and rotatory powers at 30° C.

* The acids and phenols present did not comprise more than 0.1% of the total oil and were not further investigated.

owing to the separation of camphor, was thoroughly cooled in a freezing mixture and the camphor (22.2 g.) removed by filtration, the filtrate being repeatedly re-fractionated and the camphor removed each time by cooling.†

The three fractions, after the removal of the greater part of the camphor, were systematically fractionated three times, when the following separation resulted, camphor being removed from fractions 7–12 by freezing.

No.	B.p.	Sp. gr.	n_D	$[\alpha]_D^{20}$	Composition, C, % H, %	Approx. yields, %

Loss (by difference)						10.8

As fractions 7–12 still contained camphor not removable by cooling they were treated with phenylhydrazine. For example, fraction 7 (b.p. 185°–190°, 22 g.) was mixed with alcohol (20 c.c.), phenylhydrazine (5 g.), and acetic acid (3 g.), the mixture heated on the water bath for two hours and then steam-distilled. The oil which passed over in the steam was extracted with ether, and the ether dried and evaporated. The residual oil (16 g.) distilled at 175°–180°. The residue not volatile in steam (9 g.) distilled at 250°–260° (100 mm.), and consisted of camphor phenylhydrazone.

By treating all the fractions 7–12 in this manner camphor phenylhydrazone (97 g.) was obtained, which corresponds to an additional camphor content of 3.6%. After this treatment practically the whole of the oil volatile in steam distilled below 225° at 705 mm.

Fractions 1 and 2, which were examined separately, consisted essentially of *d*- α -pinene, as confirmed by the preparation of pinene nitrosochloride, which after precipitation from chloroform solution by methyl alcohol decomposed at 109° and yielded on treatment with piperidine the nitrol-piperide, which crystallised in tablets m.p. 118°–119°. Tests for β -pinene and camphene gave negative results.

Fraction 3 was apparently free from dipentene, since it gave no dipentene tetrabromide on treatment with bromine. It yielded a small quantity of pinene nitrosochloride, whilst on treatment with phosphoric acid it gave a good precipitate of the cineol compound. Quantitative estimation indicated the presence of 0.7% of cineol (calculated on the total oil).

Fractions 4, 5, and 6 consisted mainly of dipentene and cineol; limonene, phellandrene, and terpinene could not be detected. The presence of dipentene in each fraction was proved by the isolation of the tetrabromide m.p. 125°. Cineol was estimated in fraction 4 by the phosphoric acid method,

† The method usually recommended for the determination of camphor in camphor oils (Allen, "Organic Analysis," Vol. IV, 325) invariably gave very low results owing to a considerable quantity of camphor being carried over both in the high and low boiling fractions and remaining dissolved in the oil. It was found convenient to remove such camphor by treatment with phenylhydrazine (*cf. infra*). It is hoped to test the accuracy of this as an analytical method.

which gave 1.4% (calculated on the total oil). The high rotation observed in all these fractions was due to camphor.

Fractions 7–12 were freed from camphor by means of phenylhydrazine and fractionated. The main portion distilled at 165°–167° (200 mm.), and consisted almost entirely of terpineol. A careful examination of these fractions and also of fraction 13 showed that safrol was absent.

Fraction 14 (the sesquiterpene fraction), when distilled under diminished pressure (70 mm.), was separated into two main fractions, (i) 150°–170°, (ii) 170°–185° (7%), the residue remaining in the flask being 2.2%. These two fractions were repeatedly re-fractionated, when three fractions were obtained, viz.:—(1) b.p. 151°–155° (39 mm.); sp. gr. 0.8969; n_D = 1.496, $[\alpha]_D$ = –3.0. (2) b.p. 158°–162° (40 mm.); sp. gr. 0.9014; n_D = 1.4986, $[\alpha]_D$ = –0.1. (3) b.p. 170°–210° (40 mm.).

Fraction (3) was not obtained in sufficient quantity for investigation. It was deep blue in colour, and evidently consisted mainly of the so-called "blue oil."

Fractions (1) and (2) possessed constants agreeing closely with those of caryophyllene (b.p. 148°–149° (34 mm.) sp. gr. 0.89789, n_D = 1.4965, $[\alpha]_D$ = –10.94), and the presence of this sesquiterpene was proved by the preparation of the nitrosate and nitrosochloride. The nitrosate, separated in needles from a mixture of chloroform and light petroleum, decomposed at 163° (Deussen, Ann., 1909, 369, 42, gives 162° as the melting point of α -caryophyllene nitrosate); the nitrosochloride decomposed at 158°–160°, which is the point usually found for a mixture of the α - and β -nitrosochlorides. An attempt to separate them by Deussen's method (Ann., 1907, 356, 2) was not successful, but by crystallisation from benzene, the almost pure α -nitrosochloride was obtained in fine needles decomposing at 173°. Mansukhani and Sudborough (J. Ind. Inst. Sci., 1918, 2, 43) were likewise unable to separate the two nitrosochlorides by Deussen's method. The presence of caryophyllene was further confirmed by the preparation of caryophyllene alcohol, m.p. 95°–96°. When a little of the sesquiterpene was dissolved in acetic anhydride and treated with a drop of concentrated sulphuric acid, the characteristic colour reactions of cadinene were observed, but it was not found possible to isolate any solid derivatives of this hydrocarbon.

Camphor twig oil.—The oil was deep brown in colour, and had sp. gr. 0.8777, n_D = 1.473. It was too deeply coloured for its rotatory power to be determined. After washing with alkali to remove any traces of free acids or phenols it was distilled three times, using a four-pear Young still-head, and the following fractions collected:—

No.	B.p.	Sp. gr.	n_D	$[\alpha]_D$	Yield.	Constituents.
1	155°–165°	0.8544	1.464	+22.45	20%	<i>d</i> - α -pinene
2	165°–170°	0.86	1.4662	+30.14	5.8	<i>d</i> - α -pinene (β -pinene absent).
3	170°–175°	0.8665	1.467	+35.41	5.8	dipentene, camphor.
4	175°–185°	0.8795	1.469	+38.82	5.8	dipentene, camphor.
5	185°–195°	—	1.4701	—	1.0	camphor.
6	195°–225°	—	—	—	14.2	terpineol, camphor.
7	225°–245°	—	—	—	6.5	terpineol, camphor, sesquiterpenes.
8	above 245°	—	—	—	16.3	caryophyllene cadinene.
9	camphor	—	—	—	14.2	

β -Pinene, phellandrene, terpinene, cineol, and safrol were absent from these fractions. Fraction 6

contained approximately 6% of camphor as estimated by the phenylhydrazine method, which brings the total camphor content of the oil to about 20%. The sesquiterpene fraction consisted essentially of caryophyllene; cadinene was detected by its colour reactions. The sesquiterpene distilled mainly at 160°–165° (50 mm.), and had sp. gr. 0.8987, $n_D = 1.4970$, $[\alpha]_D = -1.57^\circ$.

Camphor wood oil.—The oil used was pale yellow in colour, and had sp. gr. 0.9313, $n_D = 1.4767$, $[\alpha] = +34.44^\circ$. After washing with dilute alkali to remove the acids and phenols, the oil was repeatedly distilled, using a twelve-pear Young still-head, when the following fractions were obtained:—

No.	B.P.	Sp. gr.	n_D	$[\alpha]_D$	Yield.	Constituents.
1	155°–165°	0.8484	1.4645	+32.62	12.2	<i>d</i> - α -pinene.
2	165°–170°	0.8503	1.4668	+39.46	4.0	<i>d</i> - α -pinene
3	170°–175°	0.8561	1.4685	—	2.5	dipentene.
4	175°–185°	0.8664	1.4690	+50.31	3.7	dipentene & camphor.
5	185°–195°	—	1.4695	—	2.2	camphor.
6	195°–225°	—	—	—	24.8	camphor, terpineol, safrol.
7	225°–240°	—	—	—	7.4	safrol, sesquiterpenes.
8	above 240°	—	—	—	17.7	caryophyllene, cadinene, camphoracene.
9	camphor	—	—	—	27.0	

The following substances were absent:— β -pinene, phellandrene, terpinene, cineol. Safrol was readily detected in fractions 6 and 7 after removal of the camphor by means of phenylhydrazine. The fraction boiling at 225°–232° at 705 mm. (yield 3.5%) was oxidised with potassium permanganate in the usual manner, when piperonylic acid was obtained which, after crystallisation from hot water, melted at 227°–228° and gave a crystalline silver salt (Ag=39.4%; calc. Ag=39.8%). The sesquiterpene fraction differed from those obtained from the leaf and twig oils in that it contained a high boiling terpeno possibly identical with camphoracene. It was not present in sufficient quantity for examination. "Blue oil" was practically absent.

In conclusion the authors wish to express their thanks to Mr. Puran Singh, formerly Assistant Forest Chemist, for making the earlier experiments,

and to Messrs. Troup, Marsden, and Howard, who have collected and supplied the material used for distillation.

AN AIR-OVEN THERMO-REGULATOR.

BY H. M. ATKINSON.

The float, A, loaded slightly with mercury or small shot, carries at the top a small capillary tube, which acts as the by-pass. Gas coming through the side tube passes freely to the burner, till the pressure on the mercury reservoir resulting from the expansion of air in the tube inside the oven raises the float upwards and cuts off the main supply by either of the two methods illustrated.

The apparatus is small and compact; it need not be more than 2–2½ in. long, and avoids the soiling action of the gas on the mercury, which is often a cause of trouble in the ordinary form of regulator.

When the float is raised and cuts off the main supply, a little gas can still reach the burner passing through the hole in the side of the float and the capillary. The capillary itself can be closed or widened to any desired extent. The bulb inside the oven is best made of one or two turns of glass tubing, about $\frac{1}{16}$ in. bore, to avoid too rapid action and to equalise the temperatures inside.

MR. JOHN ALLAN IN THE CHAIR.

DISTILLATION PLANT, WITH SPECIAL REFERENCE TO THE RECTIFICATION OF ALCOHOL, ACETALDEHYDE, AND OTHER VOLATILE PRODUCTS AND CONTINUOUS ETHER MANUFACTURING PLANT.

BY STEPHANE MASFARAUD.

The object of distillation may be defined as being the separation of a volatile liquid from a non-volatile substance, and, more generally, the more or less complete separation of liquids possessing different rates of volatilisation.

In order, however, to obtain products in the highest state of purity, it is necessary to effect several consecutive distillations, a process called "fractional distillation" in the laboratory or "rectification" in industry.

Distillation of binary mixtures of immiscible liquids.

It is well known that if a mixture of water and turpentine is boiled in a still, the turpentine, b.p. 160°C ., passes over into the distillate in greater quantity than the water at a temperature below 100°C .; also that water vapour carries over mercury at a temperature below 100°C . At atmospheric pressure a mixture of ethylene dichloride with water has a fixed b.p. (75.6°C .), which is lower than that of water or of pure ethylene dichloride (82.4°).

Since the constituents of such mixtures are without action on each other, it follows that the vapour pressure, P , of the mixture is equal to the sum of the partial pressures, F and F' , of the liquid constituents at the boiling temperature, T , of the mixture. F and F' separately therefore must be less than P . Thus in the cases mentioned the boiling temperature, T , is lower than that of either of the two liquids boiling in the pure state under pressure P .

It is possible to forecast the composition of a distilled liquid. If A and B represent the respective weights of the two liquids volatilised simultaneously, and D and D' the densities of their vapours,

$$\frac{A}{B} = \frac{D}{D'} \times \frac{F}{F'}$$

and since D and D' are proportional to the respective molecular weights, M and M' ,

$$\frac{A}{B} = \frac{M F}{M' F'} \quad \text{in which } F + F' = P.$$

This statement sums up the distillation of a binary mixture of immiscible liquids.

The formula $P = F + F'$ is verified by the following experiments carried out by Gernez so long ago as 1878:—

1. Carbon bisulphide and water (CS_2 has b.p. 46.04°). $T = 43.68^{\circ}$; $P = 765.35$ mm.; $F + F' = 766.61$ mm.; $(F + F') - P = 1.29$ mm.

2. Carbon tetrachloride and water (CCl_4 has b.p. 78.1°). $T = 66.17^{\circ}$; $P = 745.45$ mm.; $F + F' = 747.36$ mm.; $(F + F') - P = 1.91$ mm.

3. Benzene and water (C_6H_6 has b.p. 80°). $T = 69.42^{\circ}$; $P = 764.44$ mm.; $F + F' = 765.92$ mm.; $(F + F') - P = 1.48$ mm.

The result of many experiments leads us to conclude that:—

- (1) The formula $\frac{A}{B} = \frac{M F}{M' F'}$

is exact, the differences observed being so slight that the law may be regarded as general.

(2) Variations of temperature do not modify that law.

(3) If, for one of the substances, M and F are small in proportion to M' , the distilled weight, B , will be less than the distilled weight, A .

Of all the substances that are dealt with in distillation processes water has the lowest value for M/F . This at once accounts for the fact that steam distillation rapidly extracts essential oils from flowers or leaves, even at a low temperature, and for the fact that water carries over toluene at 27.5° , aniline at 23° , nitrobenzene at 22.5° under 23–27 mm. pressure.

In general, then, it may be said that in all cases where, at a given temperature, the resultants of $M \times F$ and $M' \times F'$ are distinctly different the separation of the two substances by distillation is easy. If $M \times F$ and $M' \times F'$ are nearly equal, the two substances are difficult to separate.

If M is greater than M' , F must necessarily be smaller than F' .

To modify the proportions of the two substances in the distillate the ratio $M F / M' F'$ must be increased or diminished so as to make it differ from 1. If it is increased by creating conditions such that F/F' becomes larger or smaller, the equality $M F / M' F'$ must cease to exist and the two substances be more easily separable.

The question whether the ratio F/F' should be increased or diminished to effect the separation of the substances must depend on the nature of the mixed substances. Let us suppose two substances, A and B , mixed, and boiling at a temperature, T , for which $M F = M' F'$. If by increasing the pressure T is raised and in consequence A is distilled in larger proportion, it follows that if the boiling point is reduced by diminishing the pressure, B will be distilled in the major quantity.

In each particular case, therefore, the products $M \times F$ and $M' \times F'$ must be ascertained for the given mixture at the boiling point under the given pressure, so that it may be ascertained whether the boiling point must be raised or lowered in order to separate the mixed substances as rapidly as possible.

The influence of pressure is made manifest in alcohol rectifiers and especially in the distillation of wines, where it has been observed that the distillate from wines distilled under pressure has a stronger flavour. In this special case, however, a certain amount of esterification takes place, a condition favoured by the increased distillation temperature. The spirit obtained by vacuum distillation, for that reason, contains only a small amount of ester. A few esters, being insoluble, are volatilised only when the pressure, i.e., the ratio F/F' , is propitious. Generally they form a true emulsion, and with the oils properly so-called they are to be found in the vinasses and residuary waters.

Conclusions.—Given a mixture containing two immiscible liquids, of which the molecular weights are known, it is possible to determine by calculation:—

- (1) The boiling point under a given pressure;
- (2) The composition of the evolved vapours;
- (3) The composition of the residue after partial distillation; and
- (4) The best method of separating the substances, either by raising or by lowering the boiling point by varying the pressure.

We have considered, so far, only the case of a mixture of two pure liquids. The presence of dissolved salts may modify the results.

Distillation of a binary mixture of miscible liquids.

The simple laws established for mixtures of insoluble liquids cannot be applied when the liquids

are mutually soluble. In this case the laws are complex, and for a long time distillation of such mixtures was purely empirical.

Regnault divided mixtures of miscible liquids into two classes. The first class includes substances which dissolve, more or less, but of which such quantities are used that, after reciprocal saturation, two separate liquids remain. The second class consists of binary mixtures of substances which dissolve in all proportions and always resolve into a single liquid.

The vapour pressure of a mixture of water and ether, which belongs to the first class, is nearly equal to that of pure ether. The following table gives the results obtained by Regnault for this mixture:

Vapour pressure in mm.				
Temperature.	Mixture.	Water.	Ether.	
15-56° ..	362-95 ..	13-16 ..	361-4 ..	
24-21° ..	510-08 ..	25-30 ..	500-0 ..	
33-08° ..	710-62 ..	27-58 ..	711-6 ..	

With mixtures of the second class, such as ethyl alcohol and water, ethyl alcohol and ether, carbon bisulphide and water, ethyl alcohol and ether, carbon bisulphide and carbon tetrachloride, the ratio of the vapour pressure of the mixture to the sum of the vapour pressures of the two substances is nearly constant whatever may be the temperature.

Distillation of mixtures of water and ethyl alcohol.

The first important study of the principles of such distillation was made by Duclaux, who distilled a definite volume of an alcoholic liquid of known composition and collected the distillate in equal fractions, which he afterwards analysed.

term dPa may be neglected and we have $dPU = Pda + dPa$.

$$\text{Whence: } U = a + P \frac{da}{dP}$$

Tracing the curve of exhaustion and determining the angular coefficient of the tangent to that curve, we obtain U .

This method was employed by Duclaux and Sorel in studying the distillation of alcoholic liquids.

Duclaux has established the relation:—

$$\frac{da}{de} = M \frac{a}{a+e} \quad \dots \dots \dots (i)$$

in which a represents the percentage (by vol.) of alcohol in the original liquid, e that of water, da the percentage of alcohol in the vapours, and de that of water in the vapours.

The relation (i) is represented by a hyperbola of which the equation is:—

$$\frac{y}{100-y} = Mx \quad \left(y = da; \quad x = \frac{a}{a+e} \right)$$

The following values have been obtained for M with mixtures of water with certain alcohols:—

		a=not more than		M.	
Alcohol.					
Methyl	30%	..	10-9	
Ethyl	25%	..	15-4	
Propyl	10%	..	20-9	
Butyl	4%	..	41-5	
Amyl	1-6%	..	49-6	
Capryl	0-25%	..	61	

Fig. 1.

If P is the weight remaining at a particular time, a the percentage of the particular substance under examination in the mixture, and U percentage of the substance in the fractions distilled, then the weight of the substance in the original mixture must be equal to the total quantities of that substance that are found in the residue and in the vapours evolved and condensed, that is:—

$$Pa = (P - dP)(a - da) + dPU,$$

or

$$dPU = Pda + dPa - dPda.$$

But as, by hypothesis dP is infinitely small, the

If, therefore, a coefficient, k , is determined so that:—

$$k = \frac{da}{a} = \frac{\text{richness of vapour}}{\text{richness of liquid}}$$

or $da = ka$, it shows clearly the tendency of the phenomenon.

The following are some values of k as given by Sorel:—

$a=1, k=9.9; a=5, k=7.15; a=20, k=3.3; a=40, k=1.8; a=60, k=1.3; a=80, k=1.08; a=95, k=1.003; a=97, k=1.001.$

From 95% to 100%, k is very nearly equal to 1, which means that if one of the substances under distillation is present only in extremely small

GRAPHIQUE DE LA TABLE DE GROENING

Fig. 2.

quantities it is strongly retained by the substance present in abundance.

To solve problems relating to the distillation of mixtures of miscible liquids it is necessary in a series of experiments to determine the vapour

Sorel's table giving the coefficient, k , may be taken as theoretically exact, but it must not be forgotten that it is essentially theoretical, and therefore very different results may be obtained in practice.

This was first pointed out by E. Barbet (Bull. Assoc. Chim. Sucr., January, 1902) as follows:—"The coefficients of Groening and Sorel are true only for surface heating. They vary with the intensity of heating, and with the bulk of liquid used. Thus they are only true in the special circumstances under which these authors worked and between rather narrow limits."

The slower and more gentle the ebullition the more the coefficient of concentration of alcohol is raised. "The people of Charente have known for a long time that they can obtain *eau-de-vie* of higher strength by gentle heating than by violent ebullition. Gentle ebullition permits of the total exhaustion of wine, containing 10% of alcohol by vol., if only one-third of its volume be distilled, while in the laboratory M. Duclaux found that to obtain exhaustion it was necessary to distil half the volume even for wine of 5% strength. The difference was due to the different methods of applying heat to the distillation vessel."

Sorel studied the special case presented by alcohol rectification plant dealing with alcoholic liquids in industry. In these liquids, two substances predominate, water and alcohol; the impurity is present only in small quantities. If S is the weight of this third substance contained in 1 kg. of mixed vapours, and s the weight in 1 kg. of the original liquid,

$$S = ks + k's^2 + k''s^3 + k'''s^4 + \dots$$

but since s is very small, terms containing powers of s may be neglected, and the equation becomes $S = ks$.

Sorel, from the experimental data he obtained, calculated the values of k for the different alcoholic concentrations, for eight different substances, constantly maintaining s below 0.02. The appended table gives the results thus obtained.

Sorel called the coefficient, k , the "coefficient of solubility." Barbet substitutes for Sorel's "coefficient of solubility" one of much greater interest and utility, which he has termed the "coefficient of purification," as it actually shows the behaviour of alcohol during the process of purification. Barbet argues that in distillation processes the matter of special interest is the ratio of impurity of the vaporised alcohol to the impurity of the alcohol in the liquid under distillation. This ratio is not given by the coefficient k . Thus, with alcohol at 25% by volume, containing 0.01% of amyl alcohol, in relation to ethyl alcohol alone, $k=5.5$, i.e., the vapour eliminated carries with it per 100 c.c. of condensate $25 \times 5.5 \div 100 = 1.375$ c.c. of amyl alcohol. But the vapour is richer in alcohol than the liquid under

pressures of several mixtures of two of these liquids, and then to introduce the third substance and again determine the vapour pressures, etc.

distillation, being, according to Sorel, at a concentration of 67.95% by volume. The impurity of the vapours, that is, the proportion of amyl alcohol

in relation to ethyl alcohol, will therefore be $1.375 \times 100 \div 67.95 = 2.02$.

The "coefficient of purification," k' , of Barbet, is thus 2.02. This coefficient gives more exact and accurate information as to the progress of purification of the product under consideration.

Fig. 3.

Barbet has constructed a graph which gives the values of k' for the various impurities studied, and represents the relative proportions of impurity in the liquid under distillation and in the evolved vapour. If, for example, towards 65% by volume the coefficient of purification of amyl alcohol is $k' = 0.50$, the proportion of amyl alcohol in the resi-

Sorel has only examined cases where the impurity is less than 2% and his coefficients should not be applied to higher percentages. In practice also the alcoholic liquid does not contain only one impurity, but a number (acids, aldehydes, ethers, alcohols, amines, etc.), which influence each other and to a certain extent also the coefficient of purification.

All the impurities under consideration are represented by descending curves, since in proportion as the alcohol concentration increases, the temperature decreases and consequently the vapour pressure of the impurity and its tendency to entrainment decreases also. On the other hand, all the substances considered here are very soluble in alcohol and only slightly or not at all soluble in water; since their molecular weights are higher than that of water, and in pure water they form a mixture of two immiscible liquids and are rapidly carried over by vapour, k' is very great for the lower alcohol concentrations.

Cases of very complex mixtures. Natural hydrocarbons.

When the mixtures are very complex the products are only roughly fractionated by distillation. This is called the law of predominance. Some separation is certainly effected, but it is necessarily very imperfect, for if the most volatile products predominate in the vapours, they are accompanied by very heavy products.

For example, crude petroleum was distilled, and the fraction passing over on distillation from 60° to 156° C. collected separately. This fraction had sp. gr. 0.779. By a fresh fractionation this product furnished 50% of various fractions boiling up to 150°; 10% from 150° to 162°, sp. gr. 0.792; 10% b.p. 162°–200°, sp. gr. 0.806; 10% b.p. 200°–210°, sp. gr. 0.822; and 20% of residue. The fractionation in such a case as this can never be more than relative, i.e., the final mixture will be a little less complex than the initial one.

Distillation apparatus.

For discontinuous distillation the simplest still consists essentially of the boiler or cucurbit, heated directly by a furnace, or indirectly by steam, and the still-head directing the vapours through a pipe into a coil immersed in cold water.

Continuous distillation.

The columns are generally vertical, and receive the fermented mash or wine to be distilled in the upper part, being heated at the base. The liquid, in descending, meets many obstacles which subject

due is twice that in the condensate. At 25% by vol. $k' = 2.0$, and the vapour is twice as impure as the liquid. So long as $k' > 1$ the vapours contain more impurity than the liquid under distillation. When $k' = 1$, the two degrees of concentration are identical. When $k' < 1$, the impurity concentrates in the liquid.

it to contact with vapour, and escapes at the lowest part as a residue free from alcohol. Continuous distilling systems may be divided into four classes: (1) Systems with heating surfaces. (2) Bubbling systems. (3) Contact systems, including (a) horizontal columns with mechanical movement; (b) percolating columns. (4) Full columns.

Rectification.

Rectification may be discontinuous or continuous.

The *discontinuous rectifier* is only in reality a high-strength still, and contains the four essential parts of this apparatus; the boiler, the rectification column, the condenser, and the tubular cooler.

Plate with perforated caps for cylindrical columns.

Fig. 4.

In discontinuous rectifiers losses of alcohol occur which vary with the apparatus, the quality of the phlegms, the duration of the operation, etc.

Fig. 5.

Continuous rectification has the advantage of constant and invariable working, thereby ensuring regular production of uniform products with the minimum of fuel. Instead of fractionating the

liquor into ten parts more or less pure, a single rectification by the continuous process gives three

Fig. 6.

parts, the first including all the head products, the second pure alcohol, and the third all the tail products.

Fig. 7.

About forty years ago M. Barbet made the first continuous rectifier which was of practical use in

industry. His improvement consisted in providing the distillation column with an invariable regulation of the flow, and by adding to it the efficient system of purification known as "pasteurisation," or "superepuration." The continuous rectifier

Fig. 8.

yields at the "eprouvettes" all the alcohol charged into it.

Some idea of the different types of distillation and rectification apparatus generally used may be gathered from the following account of some of Barbet's apparatus:

(1) *Distilling columns.*

(a) Fig. 5. Columns for low-strength alcohol should be used in all cases where the phlegm produced is at once rectified in the same factory. When a continuous rectifier is used, the phlegm should be pasteurised, so as to expel all fermentation gases, more especially the sulphurous gases, and also to extract a small proportion of highly-concentrated aldehydes. (b) Fig. 6. Column for high-strength alcohol. This column produces in one operation alcohol of 92–94%, which is suitable for denaturation. It should also be used where the phlegm is sent away to be rectified. Two kinds of phlegm can be produced simultaneously, one ready to "denature," the other pasteurised for subsequent rectification.

(2) *Continuous alcohol rectifiers.*—These Barbet types combine in one apparatus the continuous distilling column and the rectifier for phlegms. This

combination economises pumps and tanks for phlegms. It is also provided with means for a first purification of the phlegms, so that the alcohol is submitted to three successive refinings. It therefore produces spirit of exceptional purity. Besides these there are several simpler types of the Barbet apparatus. (See fig. 7.)

(3) *Continuous rectification of wood spirit.*—

The rectification of wood spirit is based on the same principles as those given for the rectification of ethyl alcohol obtained by fermentation, and can be carried out in some of the types already described, parts of the apparatus being suitably varied. (See fig. 8.)

Instead of three, or even four, successive discontinuous rectifications, with corresponding losses, which often reach and even exceed 8% it is possible to have only one continuous rectification with no appreciable loss. A powerful type of continuous rectifier gives methyl alcohol of 99.5–99.7% containing less than 0.1% of acetone.

Rectification of petroleum and benzol.

Amongst the most important difficulties encountered in distilling crude petroleum are: (1) The high temperature required for the distillation of a heavy petroleum, which makes distillation by steam impossible unless it is carried out in a vacuum. (2) The influence of "cracking," so that the removal of low-boiling constituents can never be completed, since some light products are constantly being formed during the distillation of the heavy ones. (3) A deposit of coke is formed by the "cracking" which adheres to the sides of the still. This coking renders it necessary to stop for cleaning, and, therefore, there can be no question of a

Fig. 9.

continuous operation where direct fire-heating is required in the distillation of high-boiling paraffins such as those containing vaseline or wax.

Where direct fire heat is necessary, distillation is carried out in large stills, and the distillates are

fractionated successively according to the temperature of their formation. These fractions are, however, far from being homogeneous.

Continuous rectification of crude petroleum spirit or of light benzols.

This problem is a very simple one because it is possible to rectify by means of steam and under atmospheric pressure, provided the vaporiser of the still is adapted to high pressure. Continuous rectification will easily fractionate crude petroleum

Fig. 10.

spirit in one operation into seven portions: gasoline of sp. gr. 0.65; spirit for soldering lamps, sp. gr. 0.68; various products of sp. gr. 0.70, 0.715, 0.73, 0.74; white spirit, sp. gr. 0.75—0.76; and some burning oil, which is not distilled but is discharged from the lower part of the apparatus (fig. 9).

Sulphuric ether apparatus.

This apparatus is in use in the powder factories of Great Britain, France, Italy, Russia, etc., and in the principal factories making artificial silks. Sulphovinic acid is placed in a lead-lined still, and alcohol vapours are caused to bubble through the liquid. The vapours leaving the still are washed with caustic soda in a scrubber, and thence pass to a rectification column. Ether of sp. gr. 0.721 at 15° C. can easily be obtained. Several large apparatus of this type built by the author for the British Government are each capable of delivering 30 tons of ether per 24 hours. (See fig. 10.)

MR W. M'D. MACKEY IN THE CHAIR.

THE COMMERCIAL EXAMINATION OF SULPHONATED OILS.

BY GEORGE FENWICK PICKERING.

The whole of the published methods for the analysis of sulphonated oils can only be regarded as giving approximate results. For example, it appears generally to be taken for granted that sulphonated fatty acids are completely decomposed on boiling with aqueous hydrochloric acid, whereas this is far from being the case.

The hydrochloric acid always causes polymerisation, which unfits the resultant fat for examination. The acetyl value of the fatty acids from sulphonated castor oil may be as low as 85; in no case have I found a figure as high as the 126 given by Lewkowitsch. When the fat from one of these samples is saponified with alcoholic potash and again separated with acid the acetyl value will be between 140 and 146. This saponification and separation of the fatty acids is essential if the separated fat is to give figures in any way comparable with those of the oil sulphonated.

Among other difficulties, the estimation of water is complicated by the charring of samples made from oils of high iodine value, the formation of lactones, and in oils containing ammonia, amide formation. The volumetric process for estimating fat, although still largely used, gives results from 3 to 20% too high. The results obtained by decomposing with hydrochloric acid and shaking out with ether may be too low through formation of poly-acids, and may be too high through the taking up of hydroxyl groups, and the fat extracted with ether contains 0.75—2.75% of combined sulphuric acid.

The refractive index and fat content are proportional. A graph plotted from these is very useful.

Sulphuric acid is present in sulphonated oils as sodium sulphonates of fatty acids, as free sulphonic acids, as free sulphuric acid, as sodium or ammonium sulphate formed during neutralisation, and finally as free sodium sulphate dissolved by the oil during the washing. In the determination of total acid by the fusion method the results may be 0.5—1% too low unless care be taken and time allowed for the initial carbonisation.

The only direct method for determining combined acid is the volumetric method of Hart (J., 1917, 1139), but when the fat from this process is extracted with ether and fused with sodium carbonate 0.7—1.0% more sulphuric acid is produced. The only accurate method of estimating combined acid is by deducting the percentages of the other forms of acid from that of total acid obtained by fusion.

The process for determining free fatty acids and sulphonated oil, which consists in adding glycerol and excess of ammonia, extracting with ether, and removing the water-soluble oils and soaps by washing the ether with water, is slow, and gives a "neutral" oil with 9—13% of free fatty acids; further, the fatty acids obtained later are never free from neutral oil.

The methods described below have given reliable results in routine work:—

A few c.c. of the sample is boiled with three times its volume of hydrochloric acid until the fatty layer is quite clear. The lower layer is drawn off, diluted with water, and tested with barium chloride solution. A precipitate of barium sulphate indicates

the presence of sulphonated oil. If the oil layer obtained in the above test is free from charred particles the methods given under "oils of low iodine value" are used. When charring takes place the methods for oils of high iodine value must be used.

Water.—Distillation with xylol is the most accurate method, but drying in the oven may be used with oils of low iodine value. About 2 g. of the sample in a 1½ in. Petri dish is dried in the water oven, with frequent stirring. If ammonia is present its amount must be deducted from the loss of weight on drying.

Total fat—low iodine value oils.—About 5 g. is boiled with dilute hydrochloric acid (1:1) until the fatty layer is quite clear, allowed to cool, and extracted twice with ether, washing the ether with water until free from acid. The ether extracts are distilled, the fat dried in the water oven, cooled, and weighed.

High iodine value oils.—5 g. is dissolved in 50 c.c. of pyridine, 25 c.c. of strong hydrochloric acid added, and the mixture heated on a water bath for at least 1½ hrs., with frequent shaking; when cool the liquid is extracted twice with ether, the ether washed, distilled, and dried.

Total sulphuric acid.—This is applicable to all samples, but care is necessary if low results are to be avoided. The result cannot be reported as combined plus free acid, since it also includes all the sulphuric acid combined with soda as free sulphate.

The bottom of a 1½ in. platinum dish is covered with powdered sodium carbonate, about 2 g. of the sample is added in small drops, over the surface of the carbonate, and the oil is covered with a further

Since practically all the common salt used is converted into sodium sulphate during the washing the salts left in the oil may be reported as Na₂SO₄.

The brine extracts after titration in the preceding operations are heated to boiling, the sulphate precipitated in the usual way and calculated to sulphuric acid. The amount minus any free acid present is calculated to and reported as free sodium sulphate.

Alkalis.—Ammonia may be detected by boiling 2–3 c.c. of the sample and testing the evolved steam. To estimate the alkalis, 10 g. of the sample is dissolved in water and titrated with N/2 acid, using methyl orange as indicator. In the absence of ammonia the alkali is calculated to sodium oxide. In presence of ammonia a further 10 g. of the sample is distilled with excess of caustic soda into 25 c.c. of N/2 acid, and the result calculated to ammonia. The difference between the two results is recorded as sodium oxide.

Unsulphonated oil.—About 5 g. of the sample is dissolved in 50 c.c. of cold water, the alkali just neutralised with N/2 acid, using methyl orange as indicator, and extracted with 100 c.c. of ether. The ether is washed several times with water until all the water-soluble oil has been removed. The water layer and washings are put aside. The ether extract is mixed with 25 c.c. of water and 25 c.c. of, roughly, N/1 aqueous potash and well shaken, the soap solution separated, and the ether layer washed with water until free from soap, uniting the washings with the soap solution.

The ether, now containing only unsulphonated neutral oil, is distilled, and the residue dried and

layer of carbonate ¼ in. thick. The dish is heated, first over a luminous Argand flame until the oil is completely carbonised, then over a Teclu burner until the contents of the dish are white. The contents of the dish are washed into a large beaker, covered with a clock glass, and excess of hydrochloric acid poured down the beaker spout. The liquid is heated to boiling and precipitated with barium chloride in the usual way.

Free sulphuric acid.—About 10 g. of the sample is dissolved in 50 c.c. of ether and shaken out three times with saturated brine of known sulphuric acid content, using 50 c.c. each time. The united brine extracts are titrated with N/4 alkali, using methyl orange as indicator.

Alkali salts.—The only salts used for washing sulphonated oils are sodium sulphate and chloride.

weighed. The water-soluble matter in the flask may be salted out and the solution shaken out with a mixture of 5 pts. of ether and 1 of alcohol by vol., but it is not easy to remove the salt. The soap solution referred to above is decomposed with acid, shaken out with ether to dissolve the fatty acids, the ether washed with water, distilled, and the residue dried and weighed. These fatty acids will be found to be fairly clean. The process described above, although tedious, requires less than half the time of the inaccurate German process. The fat from all good samples of sulphonated oil should not contain more than 15% of unsulphonated oil.

The results of the examination of commercial sulphonated oils are given in the table above.

My thanks are due to Messrs. A. Hess and Bro., Ltd., in whose laboratory the above work was done.

Communications.

THE USE OF THE REFRACTOMETER IN ASCERTAINING THE PURITY OF CERTAIN REFINED EDIBLE OILS.

BY F. H. THIM, B.Sc.

By suitable refining processes, crude vegetable oils giving an acid reaction can be converted into "neutral oils" suitable for edible purposes: the greater the efficiency of the refining processes, the more nearly do these oils become colourless, tasteless, and odourless. These latter properties constitute the "quality" of the oil in question, and can be tested by suitable organoleptic methods. Though, however, a sample of oil might pass the quality tests, it is also desirable to know its purity, i.e., freedom from admixture.

Since edible oils such as palm kernel, coconut, and arachis, are now prepared in enormous quantities, mixtures of any two or of the three oils are likely to be met with. Admixture may occur inadvertently during expression of the raw material or the refining of the crude oil, but most likely during storage and transport. The presence of small quantities of any two of them in a consignment of the third oil may not impair the oil for its specific purpose, yet for control purposes a simple method of detection combining rapidity and fair accuracy would be advantageous.

With respect to mixtures of the above-mentioned oils, distillation and turbidity tests have their limitations, and are generally too complex for routine work. It is therefore necessary to choose other determinations. The determination of melting point is essential for the examination of an edible fat, and if conducted under standard conditions gives reliable and consistent results. It can give good indications of the amounts of constituents in dual mixtures such as palm kernel and arachis, coconut and arachis, or palm kernel and coconut (see tables 2, 3, and 4).

For the examination of mixtures of all three oils another "constant" is necessary in addition to the melting point. A rapid optical determination commends itself for this purpose, either refractive index or dispersive power. The determination of these by the Pulfrich refractometer yields results of high accuracy in a short time. The refractive index is of greater analytical value than the dispersive power, since it has a greater range from one oil to another. Though the latter "constant" is independent of free fatty acidity and temperature considerations, and the former is intimately dependent upon both, yet this advantage of dispersive power over refractive index is nullified in dealing with refined oils of free fatty acidity 0.04% (as lauric acid), provided the temperature is stabilised, say, at 40° C.

TABLE 1.

Constants of refined edible oils.

Oil.	Standard n _D ⁴⁰	Variation.	m.p., °C.	Free fatty acids (as lauric). %
Arachis ..	1.46235	± 0.00020	-8.0	0.05
Palm kernel ..	1.45097	± 0.00020	28.35	0.04
Coconut ..	1.44897	± 0.00010	24.85	0.03

Standard results.—Since the melting point and refractive index are to be employed in the examination of mixtures, it is necessary to have certain standards obtained for oils of known purity. The standard sample should not be prepared from crude oils already supplied without certainty as to freedom from admixture. It should be prepared from

the original raw material by extraction or expression, and the crude oil so obtained treated by laboratory methods corresponding closely to works' methods. The results in table 1 were obtained from numerous standard specimens.

Coconut oil showed the least variation in refractive index. The refractive indices of refined oils from four different copras are here quoted:—Ceylon, 1.44887; Straits, 1.44902; Singapore, 1.44887; Malabar, 1.44897.

Mixtures of refined oils.—Dual mixtures of pure palm kernel, coconut, and arachis oils were made and the melting point and refractive index determined for each. From graphs obtained by plotting melting point with percentage composition, and refractive index with percentage composition, tables 2, 3, and 4 were compiled.

TABLE 2.

Mixtures of palm kernel and arachis oils.

Palm kernel.	Arachis.	n _D ⁴⁰	m.p., °C.
100	0	1.45097	28.35
90	10	1.45211	27.95
80	20	1.45325	27.30
70	30	1.45439	26.40
60	40	1.45553	25.50
50	50	1.45666	24.35
40	60	1.45780	23.00
30	70	1.45894	20.80
20	80	1.46008	17.25
10	90	1.46122	11.60
0	100	1.46235	-8.00

It will be noted that the refractive index is directly proportional to percentage composition, and that the presence of 10% of arachis oil in palm kernel oil only lowers the melting point by 0.4° C.

50	50	1.44997	26.20
40	60	1.44977	25.95
30	70	1.44957	25.65
20	80	1.44937	25.40
10	90	1.44917	25.10
0	100	1.44897	24.85

For the three dual mixtures the refractive index shows a linear relationship with percentage composition. The relationship between melting point and percentage composition is not linear in any of the three cases. If, however, refractive index is taken as ordinate and melting point as abscissa a closed graph is obtained (fig. 1). This may be divided into various sections, and any required section used for the estimation of the constituents of either dual or triple mixtures (fig. 2). For

Graph for use with dual or triple mixtures of refined palm kernel, coconut, and arachis oils.

Fig. 1.

example, a given sample is found to have m.p. 27.0°C , $n_D^{40}=1.45150$. These values locate the point A, which at once indicates 8% of arachis oil present. The remaining 92% is then divided proportionately to the coconut-palm kernel percentage, viz., 18:82. Thus the composition of the oil sample is:—palm kernel 75%, coconut 17%, arachis 8%.

Open capillary tubes 0.7 mm. diam. were dipped 1 cm. into the sample, withdrawn and the fat allowed to solidify, keeping the tubes 1 hr. at 0°C . At the expiration of this period they were placed with the lower end 2 cm. under water level, the water being at 15°C , or lower for m.p.s. below 15°C . Electrical heating and stirring then commenced, and the melting point was recorded when the column of melted fat commenced to rise owing to hydrostatic pressure.

Summary.

1. Dual mixtures of coconut, palm kernel, and arachis oils can be accurately determined by the refractive index figure, and also by melting-point determinations.

2. Triple mixtures of the above oils can also be determined using refractive index and melting point figures. Hence the purity of these edible oils can be rapidly ascertained.

THE "SLOPE" OR "TYPE" OF THE RUBBER STRESS-STRAIN CURVE

BY DR. O. DE VRIES.

In a recent paper* Schidrowitz, Goldsbrough, and Hatschek have discussed the nature of the stress-strain curves of vulcanised rubber-sulphur mixtures, and especially the mathematical solution of these curves as belonging to the conchoid family. The figure for "slope" or "type" plays a prominent rôle in these calculations.

Doubtless the slope of the stress-strain curve is an important figure, representing as it does the increase in load necessary to produce a certain elongation. The fact that the stress-strain curve at high elongations (at least for rubber-sulphur mixtures, with which this paper deals exclusively) ends in a straight line, so that the slope of this part of the curve is a constant, gives a special importance to this figure, which represents the resistance to stretching, or the distensibility, at high elongations. The higher the figure for slope of this part of the stress-strain curve, the more easily the

* J., 1919, 3477.

Fig. 2.

Another sample gives m.p. 24.6°C , $n_D^{40}=1.44957$. This locates point B, and would indicate the sample to be coconut oil containing about 4% arachis oil.

In conclusion it must be remarked that the figures quoted throughout refer to the products of a specific process of refining, and allowance must be made at any time for natural variations in the raw material having influence upon the "constants" of the refined edible product. The refractive indices were determined by a Hilger-Pulfrich refractometer, and the melting points by a modified method. The latter determinations were conducted as follows:—

vulcanised product already stretched to ten or more times its original length, yields to a further increase of load, and the weaker it is.

Very characteristically Schidrowitz and his co-workers have called this property "type." It shows markedly the differences between higher and lower grades of rubber, and is a better index of the properties of the lower grades than the tensile strength, the figure for which, in such cases, is often uncertain because of the presence of particles of dirt etc. The different grades of plantation-rubber, in our testing work, gave the following figures for "slope" or "type," determined by the method of Schidrowitz:

	Average.	Normal figures.	Limits.
First quality crêpe ..	35.8	34—38	33—39
Smoked sheet ..	36.7	35—39	33—40
Crêpe from lump ..	37.3	35—38½	33½—40
" " tree-scrap ..	38.8	37—41	35½—44½
" " bark-rubber ..	42.9	40—43	38—47½
" " earth-rubber ..	37.6	36—39	34—40
" " washings ..	39.1	37—41	35½—46

The highest figure was 53*, found in a sample of very inferior crêpe from washings; the lowest figure, 32, is sometimes met with in crêpe from matured rubber.

Especially when figures of 40 or higher are found for slope, the sample may be expected to be inferior, and the higher figures generally indicate a rubber which on keeping is liable to become tacky. Whether in the first grades a difference in slope between, say, 35 and 38 has any practical importance, remains to be seen. Though, theoretically, a rubber with a slope of only 34 to 35 is stronger and therefore preferable, it is not yet clear whether the difference is sufficiently great to affect the manufacture.

The determination of "slope" is easy and necessitates no additional testing, as the stress-strain curve obtained in the determination of tensile strength may serve to read the slope also; and as slope represents a separate property, independent of tensile strength or rate of cure, it certainly deserves more attention than has hitherto been given to it. The more independent properties one takes into consideration, the better a substance with properties so complicated as rubber can be judged.

Moreover, it has been shown on a former occasion† that a close relationship exists between the "slope" and the permanent set, when both are determined for mixtures of 92½ rubber and 7½ sulphur, vulcanised to our standard state of cure (length of 990% at a load of 1.30 kg.; coefficient of vulcanisation appr. 5). The closer nature of this relationship has not yet been worked out, but there appears to be no doubt that this relationship is founded on the intrinsic properties of the vulcanisate, and that there is one factor—be it structure, composition, or some other—which is the cause that a certain rubber stretches easily at high elongations, and that at the same time, after releasing, it shows large deformation.

It is not yet clear which intrinsic property of the rubber is responsible for the slope, and which factors in preparation have an influence on it. From our investigations the following facts are brought out:

(1) The slope becomes greater (the rubber less resistant to stretching) by prolonged and heavy tapping.

(2) The slope decreases by maturation† (decomposition on keeping the still wet coagulum, giving a quick-curing rubber); it also decreases by the use of sulphite and bisulphite in the latex, which

prevent surface-oxidation and discoloration of the coagulum.

(3) The slope increases by coagulation with alcohol*, by the action of lower organisms causing spots on crêpe, and by traces of copper salts, causing tackiness; also by strong heating of the fresh, still wet coagulum.

It would seem that the slope is smaller (the rubber better), the purer the rubber is, and greater, the more decomposition-products are present. The exact nature of these changes is, however, far from clear; addition of foreign substances (such as gypsum or tale) to the rubber-sulphur mixture does not alter the slope, which also remains the same for mixtures with different contents of sulphur.†

The following remarks on the mathematical interpretations of Schidrowitz, Hatschek, and Goldsbrough have no bearing on the above considerations, but tend to give a much deeper meaning to the slope of the upper part of the stress-strain curve.

Before discussing these mathematical interpretations, it may be recalled that Schidrowitz and his co-workers do not use the real slope of the upper part of the stress-strain curve, but an arbitrary figure, being 0.4 (length at 1.04 kg.—length at 0.60 kg.). We have, at first, used the slope of the upper part of the stress-strain curve; when drawn on the scale of the Schopper machine (abscissæ 1 mm.=0.01 kg. per sq. mm.; ordinates 1 mm.=5 units elongation, taking original length at 100) the slope of this part of the curve, in %, is about 30. As will be easily seen, in working on the above scale, the same figure is obtained by taking length at 1.40 kg.—length at 1.20 kg., or in general (as this part of the curve is a straight line) the difference in length for an increase in load of 0.20 kg. per sq. mm. Since the appearance of a paper by Schidrowitz and Goldsbrough‡ we have adopted their method of expression to secure as far as possible uniformity in testing results. We found that the figures for slope, determined in both manners for rubber vulcanised to our standard state of cure, run parallel; the following is the relation between the two:—

TABLE I.

Slope after Schidrowitz ..	34	36	38	40	42
Slope of upper part of curve, %	27.5	29.9	32.2	34.6	37.0

Schidrowitz and his co-workers try to identify the rubber stress-strain curves as conchoidal curves, for which, at a special state of cure, $a=b$. Now it is clear at first sight that this cannot be correct, at least, not without restrictions. The rubber stress-strain curve starts from the origin in the form of an S. This is obvious in all reproductions of curves obtained on Schopper machines (and also in Schidrowitz's figs. 1 and 3, pp. 347 and 349 T, *loc. cit.*). On the Schopper machine, which is especially built for testing at high elongations, the beginning of the curve is often distorted by small irregularities (small shocks in the first stretching of the ring etc.), and is not easy to study in detail. On other machines, such as the Schwartz machine, the S-form of the lower end of the curve stands out much more clearly. This S-form is found for all states of cure; conchoidal curves, however, show it only when $a < b$; for $a=b$ the axis of ordinates (elongations) is a tangent to the conchoidal curve.

This point, showing that Schidrowitz's mathematical solution cannot be theoretically correct for the whole stress-strain curve, may, however, be regarded as of minor importance if the upper part of the curves, where "slope" is determined, and which is the most important in Schidrowitz's considerations, shows a sufficient agreement with the conchoidal curves.

* See O. de Vries, Arch. voor de Rubber Cultuur, 1918, 2, 237, 97 and 557; 1920, 4, 217.

† O. de Vries and H. J. Hellendoorn, J., 1919, 38 T; India Rubber J., 1919, 57, 1165; Arch. voor de Rubber Cultuur, 1918, 2, 783, 791; India Rubber J., 1919, 57, 505.

* J., 1919, 92 T.

† O. de Vries and H. J. Hellendoorn, J., 1917, 1260.

One of the chief points which Schidrowitz and his co-workers bring forward is that the upper ends of the stress-strain curves for different states of cure run parallel, and that the "slope," determined by their method, is a constant, not changing with increasing times of cure.

This is certainly not correct for curves obtained by our method of testing. We have on several occasions* reproduced sets of stress-strain curves which show clearly that the slope of the upper straight part is greater for less cured samples, and becomes smaller and smaller the further the sample is cured. This was regularly found to be the case in our testing of thousands of samples; Table II. gives some figures representing this decrease in slope with increasing time of cure.

The same difference may be noted in the sets of curves published by B. J. Eaton and his co-workers for mixtures of 90 parts of rubber and 10 of sulphur; though no figures are given, and the slope of the curve, in whichever form, is not determined in their testing-work, the reproductions often† show clearly enough that the end of the curve becomes less steep the more the cure is advanced. Even the set of curves reproduced by Schidrowitz‡ would seem to show a similar difference: the curves marked V. and VI. are distinctly steeper than those for further advanced cures.

Whilst therefore the upper, straight ends of the curves do not run parallel for increasing times of cure, we have further to consider whether the slope, determined by Schidrowitz's method, that is, $0.4 \times$ (length at 1.04 kg. ÷ length at 0.60 kg.), remains constant. Schidrowitz and co-workers find this to be the case in their method of testing, and give a number of examples in their Table II. (*loc. cit.*, 350 r). We do not find constancy in our testing; the slope, determined by Schidrowitz's method, increases with increasing times of cure. We have often controlled this fact for the curves obtained in testing large samples (of which slabs of two rings are used as a control in every vulcanisation), and invariably found this increase in slope for increasing times of cure.

The figures in Table II. (following) may be cited as an example. The state of cure is indicated in the first column by the position of the stress-strain curve in our usual manner, i.e., by its length at 1.30 kg. The second column gives the difference in length for 0.20 kg. increase in load, or the slope of the upper part of the stress-strain curve in %, when drawn on the scale of the Schopper machine (*cf. supra*). The third column contains the slope determined by Schidrowitz's method.

TABLE II.

Length at 1.30 kg.	Slope of upper end.	Slope (Schidrowitz).
1070	33.6	34.7
1050	32.2	35.1
1030	30.8	35.4
1010	30.1	35.7
990	29.9	36.0
970	29.7	36.35
950	29.5	36.7

The changes in both properties are clearly illustrated by this table; for the study of the exact nature of the stress-strain curves it is of importance that the slope of the upper part of the curve becomes smaller (the curve flatter) on increasing the time of cure, whilst the slope determined by Schidrowitz's method shows a gradual increase. The two methods therefore do not give results which run parallel for increasing states of cure.

It is not yet apparent what differences in method of curing or testing are the cause that figures in our case show this divergency, whilst in Schidrowitz's testing they remain constant; the mixture is nearly the same (in Schidrowitz's testing

8 sulphur on 100 rubber, in our case $7\frac{1}{2}$ on 92 $\frac{1}{2}$, or 8.1 on 100); the temperature of vulcanisation, the room-temperature during testing, and probably minor details in method of curing and testing differ.

Whilst therefore the mathematical formulæ for the stress-strain curves, evolved by Schidrowitz and his co-workers, are not strictly applicable to our testing results, there is a strong indication that these authors are nevertheless on the right track with their speculations on the deeper nature of the stress-strain curves. They conclude that for each sample there is a correct or optimum state of cure, represented by a conchoidal curve for which $a=b$, and giving an ideal balance of properties, the toughness (tenacity) equalling the limit of extension. This optimum state of cure is calculated to lie lower on the paper, the higher the figure for "slope" or "type." Now we have shown* that the maximum of tensile strength (found when vulcanising for increasing times of cure) is a property which indeed follows this law: it is found lower on the paper, the higher the figure for slope. This proves, in our view, that Schidrowitz and his co-workers, in their mathematical speculations, have arrived at the truth, though their formulæ probably present the case in too simple a form. In a former paper we have given some figures for the position of the maximum of tensile strength for samples with different slopes. As the maximum of tensile strength, in our mixture, is rather flat, it is difficult to determine the exact position of the curve, which gives a maximal tensile strength. Combining our former figures (*loc. cit.*) with later, unpublished results, we estimate the length at 1.30 kg. of the curves giving the maximum tensile strength at 992 and 957 for slopes of 36 and 40 respectively.

Schidrowitz and his co-workers give for the correct cure the following extensions at a load of 1.04 kg. per sq. mm.: 884 and 850 (*loc. cit.*, table I.) This means a length of 984 and 950 times the original; using our figures from table I. (above), and assuming (as is approximately true) that the curve has already reached its straight part at a load of 1.04 kg., we calculate the lengths at 1.30 kg. for Schidrowitz's correct cure as 1023 and 995 for slopes of 36 and 40 respectively. These figures are higher than ours, but the difference in length (distance between the curves) is very similar (38 against 35 units).

Strict comparisons are impossible, as the methods of curing and testing differed; it cannot be said whether Schidrowitz's correct cure and the maximum of tensile strength coincide or not. A relationship between the two is, however, very probable.

Summary.

The slope of the stress-strain curve, that is the increase in load necessary to obtain a certain increase in length, or, in other words, the resistance to stretching, is a property well worth attention in rubber testing. Determined after the formula of Schidrowitz and Goldsbrough it gives, besides tensile strength and rate of cure, an independent property, which is especially typical in judging lower grades, and which, by its direct relationship to permanent set, seems to have a deeper meaning.

The mathematical solution of the stress-strain curves as conchoidal curves, evolved by Schidrowitz, Goldsbrough, and Hatschek, does not strictly hold good for our method of testing; the conclusions of the above authors as to a "correct" cure are, therefore, not generally applicable. Still, the parallelism between this supposed "correct cure" and the actual maximum of tensile strength tends to show that a relationship exists, though the mathematical formulation may be more complicated than that supposed by Schidrowitz and his co-workers.

Communications.

A NOTE ON THE DETERMINATION OF DIASTATIC ACTIVITY.

BY EDWARD IVAN ROSENBLUM, M.Sc.

IN the course of an investigation into the methods of evaluation of malt substances, which was undertaken by a section of the Analytical Investigations Committee of the Australian Chemical Institute, a number of measurements were made which are of interest as bearing on the question of impurities in commercial starches, and their effect on the amylolytic activity of diastase. The fact that commercial starches usually react acid to phenolphthalein, and alkaline to methyl orange, is attributed by previous investigators to the presence of phosphates, and since these cannot be completely removed by washing with acid as in making soluble starch, and as they do not appear in the ash unless alkali carbonates have been added before ignition, they have been thought to be organic phosphorus compounds.

In their influence on the reaction, or hydron concentration of the starch solutions, however, they may be considered as mixtures of ammonium phosphates, and in most cases behave as if containing both $(\text{NH}_4)_2\text{HPO}_4$ and $\text{NH}_4\text{H}_2\text{PO}_4$. That these impurities, although small in amount, have a very marked influence on the determination of diastatic power is shown by Ford (J., 1901, 414), who found figures varying from 6 to 31 as the diastatic power (Lintner's scale) of starches bought from different dealers, and so liable to be used in the evaluation of malt.

The conversion of potato starch into soluble starch by washing, first with water, then with 0.5% sodium hydroxide, with water again, digesting for seven days with hydrochloric acid of sp. gr. 1.037, and finally washing free from chlorides with distilled water, gives a product which, although considerably improved, still shows, when boiled with water, a slight acidity to phenolphthalein which it appears necessary to attribute to the presence of phosphates. This is shown by the following figures for starches used in the subsequent experiments of this research:—

	Potato starch	Soluble starch
Sugars and dextrin	Nil.	Nil.
Ash	0.33%	0.10%
1 g. requires—		
c.c. N/100 HCl to methyl red	2.2 c.c.	Neutral.
c.c. N/100 NaOH to phenolphthalein	1.5 c.c.	1.0 c.c.

It has been shown by Ford (*loc. cit.*), and more recently by Small (J. Amer. Chem. Soc., 1919, 41, 113), that it is possible to prepare a more highly purified soluble starch, in the one case by repeated precipitation with alcohol, and in the other by digestion with alcoholic hydrochloric acid instead of the aqueous acid.

These methods are not very suitable for the manufacture of commercial soluble starch, or for defining a standard "soluble starch" to be used in conjunction with a standard method, and it would be preferable, if possible, to add a definite quantity of some amphoteric electrolyte which would ensure a constant acidity in the digesting solution. Asparagine has been found to have considerable effect in this direction, and lactic acid has also been suggested, both, of course, operating by increasing the hydron concentration; but the addition of ammonium phosphates would be more practical if proved to be effective. With this end in view the following experiments have been conducted.

The influence of hydrogen ion concentration.

Sherman, Thomas, and Baldwin (J. Amer. Chem. Soc., 1919, 41, 231) have investigated the influence of hydron concentration on the activity of malt diastase. They conclude that the maximum activity in a 30-minute test at 40° C. is obtained when the hydrogen ion concentration is $10^{-4.4}$ to $10^{-4.3}$, or in Sørensen's notation $p_H = 4.4$ to 4.5, a condition which they obtained by the addition of 0.06 mol. of NaH_2PO_4 per litre. A few of their results are as follows:—

Final conc., mols. per litre,					Activity of malt amylase.
H_2PO_4	NaH_2PO_4	Na_2HPO_4	Na_2CO_3	p_H	
0.0167	0.06			2.34	0
0.0057	0.06			2.70	99
0.0007	0.06			4.06	1000
	0.067			4.47	1101
	0.065	0.0007		4.80	1100
	0.033	0.033		6.65	969
		0.02		8.25	210
		0.05	0.0004	8.80	64
		0.05	0.0025	9.33	0

Their measurements of p_H were carried out directly by electro-potential methods, and it is of interest to compare the p_H values of common indicators, as given in Lewis' "Physical Chemistry":—

	p_H .
Methyl orange	4.5—5.5
red	5.7—6.4
Litmus	6.5—7.5
Phenolphthalein	8.2—9.0
Thymolphthalein	10.5—11.5

It should be possible, therefore, to define the p_H value of the solution, approximately at least, by means of indicators.

The first experiments in this investigation were made with a malt extract (A) of the following characteristics: Total solids, 78.0%; sugars calc., as maltose, 65.6%; ash, 2.1%. This was itself amphoteric in reaction and when 5 g. dissolved in 50 c.c. of water was titrated the following results were obtained. They are shown together with the figures for a second sample (B) employed at a later stage in the work.

Reaction of malt extracts.

Reaction to indicator.	Acid or alkali added.	Sample "A."	Sample "B."
With methyl orange to red shade	N/10 HCl	4.06 c.c.	3.75 c.c.
With methyl orange to orange shade ..		3.04 c.c.	—
Neutral to methyl red ..	N/10 NaOH	1.31 c.c.	2.0 c.c.
Neutral to litmus		4.40 c.c.	—
With litmus to a blue shade ..		7.33 c.c.	—
Neutral to phenolphthalein ..		13.30 c.c.	13.0 c.c.

The end-points with phenolphthalein and methyl red were sharp, those with methyl orange and litmus indefinite. The reaction of malt extract, as of starch, is considered to be due to acid phosphates of which the ash is largely constituted and which are believed to exist as ammonium phosphates in the extract itself.

A series of solutions were now made up in which the malt extract as a 0.5% solution was brought to the end-points of the different indicators with N/100 acid or alkali.

Determination of diastatic power.

Twenty c.c. of each solution, containing 0.1 g. of malt extract, was added to a starch solution containing 1 g. of dry starch in 80 c.c. which had been prepared by boiling and then cooling to 46° C., and the flask containing it was immersed in a thermostat at that temperature for exactly 30 mins. At the end of that time the diastatic action was stopped by the addition of a few drops of 20% sodium hydroxide solution, the volume adjusted to exactly 100 c.c., and the solution titrated with Fehling's solution.

This titration is known as T_D and a further titration of a 1% solution of the malt extract alone gives T_M , a measure of the sugar originally contained in the extract.

The formula $9531(1/T_D - 1/10T_M)$ gives the diastatic power, being 100 times the amount of starch converted by one part of malt extract under the above conditions, and this quantity is the diastatic power quoted in the succeeding tables.

The above method is essentially that of Harrison and Gair (Pharm. J., 1906, 94, 6) which is the official method of the Victorian Pure Food Regulations for testing commercial malt extracts.

Diastatic power of malt extract "A."

TABLE I.

Malt solution neutralised with N/100 acid or alkali.

Indicator.	Reaction.	Starch used in digestion	Potato	Soluble.
—	Un-neutralised	200	302	
Methyl orange	Faintly acid	120	150	
—	Neutral	164	207	
Methyl red	—	313	259	
Litmus	—	280	286	
—	Faintly alkaline	246	252	
Phenolphthalein	Neutral	120	185	

The results show a maximum about the region of methyl red, while the difference between the un-neutralised solutions is striking as showing the result of using two different starches in a normal estimation. The reaction of the starch was not corrected in the above series because of the indefiniteness of the endpoints.

However, the following measurements, where the fairly clear end-points alone are included, are not without significance:—

TABLE II.

*Diastatic power of malt extract "A."
Both starch and malt solutions neutralised.*

Indicator.	End-point.	Potato starch.
—	Un-neutralised	200
Methyl orange	Faintly acid	69
Methyl red	Neutral	189
Phenolphthalein	—	140

It should be remembered that the reactions of the un-neutralised solutions to methyl red are faintly acid for the malt extract, neutral for the soluble starch, and alkaline for the potato starch.

TABLE IV.

Diastatic power of diastase. Soluble starch digestion with added phosphates.

No.	Indicator.	Reaction.	Moles per litre.				Diastatic power.
			H ₃ PO ₄ .	NH ₄ H ₂ PO ₄ .	(NH ₄) ₂ HPO ₄ .	Ammonia.

7.	Litmus	Neutral	—	—	—	—	75000
8.	—	Intermediate	—	0.0034	0.0015	—	Below 30
9.	—	—	—	0.0017	0.0015	—	0
10.	—	—	—	—	0.0015	—	0
11.	Litmus	Faintly alkaline	—	—	0.0030	—	0
12.	Phenolphthalein	Neutral	—	—	0.0030	0.0014	0

The addition of ammonium phosphates.

With the same malt extract and potato starch, the results shown in Table III. were obtained.

The preceding work suggested the advisability of a further series working with soluble starch and purified diastase, so as to reduce as far as possible the phosphates occurring naturally in the reaction mixture.

TABLE III.

*Addition of ammonium phosphates.

—	0.0660	—	176
—	0.0880	—	129
—	0.1760	—	0
—	0.0880	0.025	122

The diastase was prepared by Wroblewski's method as follows: 900 g. of air-dried, unkilned barley malt was ground and extracted once with 70% alcohol, the extract being rejected. It was then treated twice with 45% alcohol, and the diastase precipitated from this by adding 95% alcohol until the sp. gr. reached 0.890. The precipitate was washed with 95% alcohol, twice with absolute alcohol, and finally three times with freshly re-distilled ether. After drying in the air 2.5 g. was obtained.

This was not completely soluble in water, but the diastase readily dissolved from it and the preparation showed a Harrison and Gair value of 7450 when tested with soluble starch. The mixture of diastase solution and soluble starch solution was found to be faintly alkaline to methyl red and faintly acid to phenolphthalein. By titration with 1% solutions of H₃PO₄, NH₄H₂PO₄, (NH₄)₂HPO₄, and ammonia the quantities of these reagents necessary to bring the mixture to the different end-points were found, and these quantities were subsequently added when effecting the digestion.

In the results recorded as zero the reduction of 10 c.c. of Fehling's solution on boiling with 100 c.c. of digested starch solution was imperceptible. In the case of No. 8, there was a slight reduction which was judged by a comparative test to represent the diastatic power shown.

The figures show that a slight acidity to methyl red, as attained by the addition of ammonium dihydrogen phosphate, is the optimum reaction for the solution undergoing digestion, the activity falling off sharply when sufficient phosphoric acid is added to make the mixture neutral to methyl orange.

The amount of ammonium dihydrogen phosphate added alone varied in the above series from 0.0051 to 0.0348 mole per litre, or 0.06 to 0.40 g. per 100 c.c.

Further experiments were designed to show what was the maximum amount of phosphate allowable or the concentration of ammonium dihydrogen phosphate at which the diastatic power ceased to rise.

The difference in the "blanks" of the different series is partly due to the fact that different diastase solutions, prepared by filtration after shaking the diastase with water, were used. It is possible that differences in the glass of the flasks used may have been a contributory factor, although flasks of resistance glass were used.

TABLE V.

NH ₄ H ₂ PO ₄ added.		Diastatic power by Harrison and Gair method		10- ² Series III.
%	Mols. per litre.	Series I.	Series II.	
0	0	71	75	71
0.001	0.000087	68	—	—
0.0025	0.00022	65.7	—	—
0.005	0.00044	67.6	—	—
0.0075	0.00066	69.6	—	—
0.01	0.00087	72.8	—	—
0.025	0.0022	—	—	71.6
0.06	0.0052	—	82.2	—
0.10	0.0087	—	—	80.1 (b)
0.20	0.0174	—	86.3	—
0.30	0.0261	—	—	74.5
0.40	0.0348	—	86.3	—
0.80	0.052	—	—	70.0
1.00	0.087	—	—	63.6

An initial fall at very low concentration is followed by a rise to an apparent maximum at about 0.2 to 0.5% NH₄H₂PO₄.

To determine whether this fall was due rather to increase of molecular concentration than to increased hydrogen-ion concentration, a final series was undertaken in which diammonium hydrogen phosphate was also added in a small proportion.

TABLE VI.

NH ₄ H ₂ PO ₄		(NH ₄) ₂ HPO ₄		D.P. x 10- ²
%	Mols. per litre.	%	Mols. per litre.	
0	0	0	0	82.2
0.30	0.026	0	0	82.2
0.30	0.026	0.015	0.00114	54.4
0.50	0.044	0	0	86.6
0.50	0.044	0.005	0.00038	82.2
1.00	0.087	0	0	86.6
1.00	0.087	0.010	0.00076	82.2
1.00	0.087	0.050	0.0038	75.6

In all the above experiments, the titrations are correct to within 0.2 c.c. of sugar solution to 10 c.c. of Fehling's solution, representing an error of about 150 in the diastatic power.

Although the results in this table are not entirely in accord with those of the last, it appears that in general the diastatic activity increases with the addition of ammonium dihydrogen phosphate up to the region of 0.5% of the salt, and it is possible that, as suggested by previous investigators, the fall at higher concentrations occurs when a certain molecular concentration is exceeded.

It seemed reasonable, therefore, to test the addition of 0.5% of acid ammonium phosphate in the estimation of the diastatic power of some routine malt extracts.

TABLE VII.

Diastatic power of malt extracts with added acid ammonium phosphate.

No.	Potato starch.		Soluble starch.	
	No addition.	0.5% added.	No addition.	0.5% added
A.	200	—	302	—
B.	215	347	412	306
C.	518	871	611	909
D.	500	774	595	774
E.	—	—	463	614
F.	—	—	382	435

Hence the addition of phosphate, as well as raising the diastatic power by establishing a favourable and constant hydrogen-ion concentration, goes far to equalise the divergent results obtained with soluble and potato starches.

With malt extract "B" and soluble starch, the addition of phosphate causes a fall in D.P., an anomalous result which recurred in a series with different starches, also digested with sample "B."

TABLE VIII.

Diastatic power of malt extract "B" with and without 0.5% NH₄H₂PO₄.

Summary.

1. The difference in the hydrogen-ion concentration of starches due to the acid salts they contain renders the estimation of diastatic activity by the digestion of starch uncertain.

2. When estimations are conducted by the Harrison and Gair method the diastatic power is at a maximum when the digesting solution has a faintly acid reaction to methyl red but is alkaline to methyl orange.

3. This condition may be secured by the addition of ammonium dihydrogen phosphate, and if 0.5% of the salt is added a constant acidity and, in most cases, an optimum activity are assured, and the difference due to the divergent reactions of different starches is neutralised.

The thanks of the author are due to Professor Masson, Dr. Heber-Green, and the members of the Malt Analysis Section for helpful criticism, and to C. S. Callaghan, who carried out most of the determinations of diastatic power.

THE PREPARATION OF THIOPHOSGENE FROM THIOCARBONYL TETRACHLORIDE.

BY PERCY FARADAY FRANKLAND, FREDERICK HORACE GARNER, FREDERICK CHALLENGER, AND DOROTHY WEBSTER.

When perchloromethyl mercaptan (thiocarbonyl tetrachloride) CCl₄.SCl undergoes reduction two chlorine atoms are removed and thiophosgene is obtained. The literature points to the use of tin and hydrochloric acid as employed by Klason (Ber., 1887, 20, 2380) as being the most promising method, although Kern and Sandoz (F.P. 5.430 of 1887; Monit. Scient., 1887, 4, 1328; and Friedländer's "Fortschritte der Teerfarben Fabrikation," 1877—1887, p. 96) employed either stannous chloride and hydrochloric acid, iron filings and acetic acid, or any mixture which produces hydrogen. These communications contain no information as to the yields to be expected.

By the action of silver dust on thiocarbonyl tetrachloride Rathke (Annalen, 1873, 167, 201) obtained thiophosgene in small amounts, as also James (Trans. Chem. Soc., 1887, 51, 268), by the action of chlorine on methyl thiocyanate. By heating carbon bisulphide and phosphorus pentachloride in sealed tubes at 100° thiophosgene and thiophosphoryl chloride are produced.

The formation of thiophosgene during the chlorination of carbon bisulphide has been noticed by Rathke (*loc. cit.*) and by three of the present authors (J., 1920, 257 T), but owing to the small quantity produced and the simultaneous presence of carbon tetrachloride, this method is entirely unsuited to its preparation even on a small scale.

The present paper contains a summary of the results we have obtained by the use of tin and hydrochloric acid as reducing agent. This method appears to be preferable to any other that we have investigated. The yield of thiophosgene usually obtained is 55—60%, while varying amounts (20—35%) of thiocarbonyl tetrachloride may be recovered.

Our method of experiment was as follows:—All the low-boiling impurities in the crude thiocarbonyl tetrachloride (J., 1920, 257 τ) were removed by fractionation with a 12-bulb column, and the residue boiling above 140° was used for the preparation of thiophosgene without further purification.

Granulated tin and hydrochloric acid in the desired proportions were heated in a large flask (not more than half-filled) until hydrogen was freely evolved. On addition of a little CSCl_4 from a dropping funnel a lively reaction ensued, thiophosgene distilling and being condensed in a series of well-cooled receivers. Very little CSCl_4 should be added until thiophosgene begins to distil over, otherwise the reaction may become too vigorous and efficient condensation impossible. When all the CSCl_4 had been added, the mixture was heated till distillation of thiophosgene ceased. After separation from the water, the thiophosgene was dried over calcium chloride and distilled, the fraction boiling below 110° being collected. After a second fractionation this yields practically pure thiophosgene. The residue boiling above 110° consists mainly of CSCl_4 , and may be used again.

The rate of addition of CSCl_4 to the mixture of tin and hydrochloric acid exerts some influence on the yield. Rapid addition (involving rapid formation of thiophosgene) gives rise to almost the same yield of thiophosgene as when the CSCl_4 is added slowly; a greater total yield of thiophosgene and CSCl_4 is, however, obtained. In experiments with 550 g. of CSCl_4 , 350 g. of tin and 1000 c.c. of concentrated hydrochloric acid, yields of 58, 61.5, and 57% of CSCl_4 were obtained when the time of addition of CSCl_4 was $1\frac{1}{2}$ hrs., 1 hr., and 20 mins., respectively; the amounts of CSCl_4 recovered were 8, 8, and 31%, respectively. With 550 g. of CSCl_4 , 175 g. of tin, and 750 c.c. of acid, the respective yields for the above times of addition were 46, 55, and 54%, with recoveries of 36, 25, and 33% of unchanged CSCl_4 . The CSCl_4 should, therefore, be added as rapidly as is compatible with efficient condensation of the distillate, although the rate of addition seems to have less influence when the proportion of tin to CSCl_4 is smaller.

Variation of the proportion of tin to CSCl_4 .—Using one atomic proportion of tin to one mol. of CSCl_4 and more hydrochloric acid than is required to dissolve the tin, yields of 54–60% of thiophosgene and 18–29% unchanged CSCl_4 were obtained. On the other hand, with half an atomic proportion of tin, one mol. of CSCl_4 ,* and excess of hydrochloric acid, the yield of thiophosgene was 50–53% and unchanged CSCl_4 33–37%. The total percentage yield (i.e., CSCl_2 plus CSCl_4) is, within certain limits, almost independent of any alteration in the ratio $\text{Sn}:\text{CSCl}_4$. In cases where this ratio is 0.5:1, however, it appears to be clearly established that (provided the rate of addition of the CSCl_4 and the other factors of the experiment remain unchanged) the amount of CSCl_2 obtained is slightly, but distinctly smaller than with higher ratios, a corresponding increase in the recovered CSCl_4 being noticed. By employing this smaller ratio, it is obvious, however, that a very great economy in the use of a rather expensive metal can be effected. Alteration of the ratio to 0.75:1 offers no special advantage, the yields of CSCl_2 and CSCl_4 being 56–58% and 30–31% respectively; the same would appear to be the case when 1.5 atomic proportions of tin are employed, the yields in one experiment being 59% and 20%, respectively.

* The proportion of $\frac{1}{2}$ atom tin : 1 mol. CSCl_4 is based on the assumption that both the nascent hydrogen and stannous chloride produced by action of hydrochloric acid on tin, are equally effective in carrying out the reduction; the proportion 1 atom tin : 1 mol. CSCl_4 assumes that only the stannous chloride or the hydrogen is effective in this way.

Variation in the concentration of the hydrochloric acid used.—In all the experiments in this series, 550 g. of CSCl_4 (1 mol.) and 175 g. of tin ($\frac{1}{2}$ atom) were employed. It was found that if ordinary commercial acid (28%) diluted with an equal volume of water is used for the reduction a yield of 53% of thiophosgene and of 38% of unchanged CSCl_4 may be obtained, if acid equal to 148% of the amount theoretically required to dissolve the tin (*viz.*, 500 c.c.) be employed. Using this amount of acid we find that dilution with $1\frac{1}{2}$ volumes of water reduces the yield of thiophosgene to 41%, with 45% of CSCl_4 recovered. Using no acid at all, but only tin and water, the yield is 25% of thiophosgene and 68% of unchanged CSCl_4 .

It appears to be of no advantage to use more than 500 c.c. of acid, the yield with 750 c.c. being only 52%. On the contrary, the reduction may be effected with less acid than is required to dissolve the tin; *e.g.*, when 250 c.c. of acid was employed a yield of 51% of CSCl_2 with 42% of unchanged CSCl_4 was obtained, whilst with only 100 c.c. (30%) the yields were 33% and 61%, respectively, but in this case the mixture became solid before all the tin had dissolved; under these circumstances increased yields were obtained by steam injection (*cf. infra*).

Use of steam for heating the reduction mixture.—Instead of heating the reaction mixture directly, steam may be introduced for this purpose with good results. Thus, with half an atom of tin to one molecule of CSCl_4 and only 30% of the amount of commercial hydrochloric acid theoretically required to dissolve the tin, a yield of 50% of thiophosgene with 39% of unchanged CSCl_4 has been obtained, solidification of the mixture being prevented.

Use of stannous chloride and hydrochloric acid as reducing agent.—A mixture of 200 g. of CSCl_4 , 270 g. of crystallised stannous chloride, 100 g. of 28% hydrochloric acid, and 70 g. of water was stirred continuously for 12 hrs. at 30° – 35° C. Yields of 56 and 58% of thiophosgene were obtained, but only 5 and 5.5% of CSCl_4 was recovered unchanged.

Use of iron and acetic acid as reducing agent (Patent specification of Kern and Sandoz).—Iron filings were slowly added to a well stirred mixture of CSCl_4 and dilute acetic acid at 35° – 40° . Yields of thiophosgene varying from 44 to 51% were obtained, but no CSCl_4 was recovered. The thiophosgene thus obtained may contain some carbon tetrachloride. We have not specially examined the product in this case. In the last two methods, the use of hot concentrated hydrochloric acid is avoided, but the yields are lower than those obtained by the use of tin and hydrochloric acid.

Use of hydrogen sulphide as a reducing agent.—By prolonged passage of hydrogen sulphide over CSCl_4 mixed with 1% of finely divided charcoal and a quantity of dried pumice at 100° – 105° , a yield of 51% of fairly pure thiophosgene and 38% of CSCl_4 was obtained; some sulphur chloride was simultaneously produced. The thiophosgene in this case contained a little carbon tetrachloride.

The action of metallic copper on CSCl_4 gives rise to considerable quantities of thiophosgene, although Rathke states that silver powder is more satisfactory. It would appear from our preliminary experiments that the best yields are obtained when one atomic proportion of copper and one mol. of CSCl_4 are employed, yields of 49, 65, and 71% of thiophosgene being obtained with 2, 1.5, and 1 atomic proportions of copper bronze (commercial finely-divided metallic copper) respectively. Another experiment with larger quantities and one atom of copper bronze gave a yield of only 49%, however, and the reaction proceeded much more slowly, giving rise to a by-product, probably hexachloromethyl disulphide, $\text{CCl}_3\text{S}_2\text{CCl}_3$.

In most of the experiments the copper bronze was gradually added to the thiocarbonyl tetra-

chloride contained in a flask fitted with a reflux condenser. The reaction occurred without the application of heat, but the mixture was heated on the water-bath for about an hour after all the copper bronze had been added. Water was finally added, when the temperature rose and thiophosgene distilled. When CSCl_4 , water, and copper bronze are mixed in the cold a mass of yellow crystals is obtained. On heating, these disappear, and thiophosgene begins to distil. Similar crystals are formed when water is added to a mixture of CSCl_4 and copper dust which has been heated.

When CSCl_4 is treated with zinc dust under various conditions small amounts of thiophosgene are produced. In one experiment a yield of about 20% was obtained, but all other attempts were much less satisfactory. Rathko (*ibid.*, 201) obtained very little thiophosgene by the use of zinc at 160°C .

Fractionation of crude thiophosgene.—About 2320 g. of crude thiophosgene (b.p. below 110°), obtained by the use of tin and hydrochloric acid, was submitted to several fractionations with the following result:—(1) Below 72°C , 34 g.; (2) 72° – 76° , 2063 g.; (3) 76° – 110° , 81 g.; (4) above 110° , 128 g. (chiefly CSCl_4). Fraction (2) had sp. gr. 1.509 at 15° . Billetter and Strohl (Ber., 1888, 21, 102) give the sp. gr. of thiophosgene obtained from CSCl_4 , stannous chloride, and hydrochloric acid as 1.5085 at 15° . Commercial thiophosgene obtained from the firm of Kern and Sandoz (Basle) is stated to contain some carbon tetrachloride (Bergreen, Ber., 1888, 21, 337).

The authors desire to express their thanks to the War Office for sanctioning the publication of this paper.

CALCULATIONS INVOLVED IN THE PREPARATION OF ACID MIXTURES USED IN THE MANUFACTURE OF NITROCOTTON.

BY WILLIAM YOUNG.

In the process of preparing the nitration mixtures, spent or refuse acid from the manufacture of nitrocotton receives a preliminary adjustment by the addition of fuming nitric acid and oleum. This treatment corrects the composition of the refuse acid, bringing it somewhere near the composition specified for the nitration process. The corrected mixture, or "bulked acid," as it is called, may prove to fall within the limits allowed in the specification laid down for the nitrating mixture, but it may not do so and will therefore require further correction, which is effected by addition of nitric acid, oleum, or refuse acid, or usually of two of these acids, in calculated proportions. The use of water is avoided, except under special circumstances.

The following algebraic method has been used for the calculation of the proportional parts at a large explosives factory with satisfactory results. After trial it has proved much less laborious than the arithmetical method and more adaptable to changing conditions than the graphical method, and with certain justifiable assumptions it can be used for constructing tables from which the proportional parts may be written down.

The method is most easily demonstrated by the working of examples, and, for the sake of convenience, the abbreviations N/A, S/A, R/A, M/A and B/A will be used respectively for nitric acid, oleum, refuse acid, specified mixed acid, and the "bulked acid" referred to above.

Example 1: A batch of bulked acid is found to require correction by means of 90% nitric acid and

20% oleum to bring it to a certain specified composition. Let the required proportions be 100 parts of bulked acid, x parts of oleum and y parts of nitric acid, on mixing which $100+x+y$ parts of the specified mixed acid will be obtained. Two independent equations are available for finding the values of x and y . The example is worked out as follows:—

	Acid.	B/A.	S/A.	N/A.	M/A.
Analysis	(% HNO_3)	22.0	0.0	90.0	23.0
	(% H_2SO_4)	66.0	104.5	0.0	67.0
	(% H_2O)	12.0	-4.5	10.0	10.0
		100.0	100.0	100.0	100.0

The equation connecting HNO_3 contents is:—

$$100 \times \frac{22.0}{100} + x \times \frac{0.0}{100} + y \times \frac{90.0}{100} = \frac{23(100+x+y)}{100}$$

Rewritten, this equation becomes $-23x + 67y = 100$
Similarly, the equation from H_2O contents becomes $14.5x = 200$

Solving these equations, $x=13.793$ and $y=6.228$. The required proportions are therefore 100 parts of bulked acid, 13.793 parts of oleum, and 6.228 parts of nitric acid.

Example 2: A general case in which the correcting acids are refuse acid of known composition and 92% nitric acid. Proceeding as before, we have the following:—

	Acid.	B/A.	R/A.	N/A.	M/A.
Analysis	(% HNO_3)	a	19.0	92.0	23.0
	(% H_2SO_4)	b	68.0	0.0	67.0
	(% H_2O)	c	13.0	8.0	10.0
		100	100.0	100.0	100.0

The HNO_3 and the H_2O contents furnish two equations, viz.:—

$$4x - 69y = 100(a - 23) \dots (1), \text{ connecting } \text{HNO}_3 \text{ contents,}$$

$$\text{and } 3x - 2y = 100(10 - c) \dots (2), \text{ connecting } \text{H}_2\text{O} \text{ contents.}$$

Solving equations (1) and (2), we find

$$x = 34.673(10 - c) - 1.005(a - 23),$$

$$\text{and } y = 2.010(10 - c) - 1.508(a - 23).$$

These general formulæ for x and y may now be used for drawing up tables, on the assumption that the compositions of the correcting acids and the specified mixed acid are constant. This assumption is dealt with later.

Construction of tables:

In practice the terms $(10 - c)$ and $(a - 23)$ are usually of small magnitude, and a working table from which the proportional parts of correcting acids can practically be read off is easily constructed.

The following skeleton table is drawn up for the conditions given in Example 2:—

TABLE 1.

Parts of correcting acids per 100 parts of bulked acid.

$$\text{Parts refuse acid} = 34.673(10 - c) - 1.005(a - 23).$$

$$\text{Parts nitric acid} = 2.010(10 - c) - 1.508(a - 23).$$

$(10 - c)$ or $(a - 23) =$	0.01	0.02	0.03	0.1	0.2	0.3	1.0	2.0
$34.673(10 - c) =$	0.35	0.69	1.01	3.47	6.01	10.40	34.67	69.35
$-1.005(a - 23) =$	-0.01	-0.02	-0.03	-0.10	-0.20	-0.30	-1.01	-2.01
$2.010(10 - c) =$	0.02	0.04	0.06	0.20	0.40	0.60	2.01	4.02
$-1.508(a - 23) =$	-0.02	-0.03	-0.05	-0.15	-0.30	-0.45	-1.51	-3.01

In Example 2, if $a=22.65$ and $c=9.85$, then $(a-23)=-0.35$ and $(10-c)=0.15$. Using the formulae or the completed table it will be found that 5.55 parts of refuse acid and 0.83 part of nitric acid are required to correct 100 parts of bulked acid.

Similar tables can be constructed for correction (1) with oleum and nitric acid, and (2) with oleum and refuse acid.

If in using any table or formula negative results are obtained, correction is impossible with the acids represented in the table, and must be carried out by some other combination of acids. For instance, in Example 2, if $a=22.65$ and $c=10.55$, oleum and nitric acid are required for correction, and Table 1 would give a negative result.

The use of tables is possible on the assumption that the refuse acid, oleum, and nitric acid are constant as regards composition. In practice this is never the case, but variations within $\pm 2\%$ of the average compositions have little effect, as is shown in Table 2.

TABLE 2.

1000 lb. of nitric acid added to 100,000 lb. of mixed acid. Calculated effect of a 2% variation in the strength of the nitric acid on the composition of the resulting mixture.

Composition of the original mixed acid.	Composition after addition of		Variations in resulting composition.
	1000 lb. of 90% N/A.	1000 lb. of 92% N/A.	
22.0% HNO_3 68.0 % H_2SO_4 10.0 % H_2O	22.673 % HNO_3 67.327 % H_2SO_4 10.000 % H_2O	22.693% HNO_3 67.327% H_2SO_4 9.980% H_2O	+0.020% HNO_3 +0.000% H_2SO_4 -0.020 % H_2O
100.0	100.000	100.000	0.000

The limitations of the method will be obvious to chemists employed in acid-control laboratories.

The author desires to express his thanks to the Research Committee of Messrs. Nobel's Explosives Co. for their kind permission to publish this method, and especially to Mr. W. Rintoul and Capt. J. M. Weir for the interest they took in its development and application.

LABORATORY APPARATUS FOR PREPARING ELECTROLYTIC HYDROGEN.

BY WILLIAM GEORGE PALMER.

The apparatus consists of an unglazed earthenware pot, 3 in. \times 7 in., in the closed end of which three holes are drilled, one at the centre of about $\frac{1}{2}$ in. bore, and two at the outer edges each of about $\frac{1}{4}$ in. bore. For $2\frac{1}{2}$ in. from the open end of the pot vertical rows of small holes (about $\frac{3}{16}$ in. diameter) are also drilled. The material of the pot is made gas-tight by soaking in melted paraffin wax. A large sheet of parchment paper (which is to form the real diaphragm of the cell) is then closely wrapped round the pot so as to cover the vertical rows of holes, and held in position by rubber bands.

The electrodes are formed of stout sheet nickel beaten into cylindrical form. The cathode is supported with its lower edge well inside the pot, by leads passing through glass tubes cemented with sealing wax into the $\frac{1}{4}$ -in. holes in the base of the pot.

The centre hole of the pot having been provided with a rubber bung carrying a bulb delivery tube for the hydrogen, the pot (containing the cathode inside) is immersed with the open end downwards in about 300 c.c. of a 5–10% aqueous solution of caustic potash contained in a beaker of one litre capacity.

The pot is supported by a glass triangle standing on the bottom of the beaker. The cylindrical anode is now fitted into the beaker outside the pot so that its lower edge is about $\frac{1}{2}$ in. above the lower edge of the pot. A distance of about $\frac{1}{4}$ in. is left between the parchment paper and the anode.

It is important to steep the anode in concentrated nitric acid for $\frac{1}{2}$ hr. before making up the cell. If this is not done the anode readily becomes attacked when a large current is used. The cell is cooled by immersion in a large outer vessel of cold water. The strength of the electrolyte should not be less than 5%, and it is preferable to work at temperatures between 25° and 30° C.

A current of 8–10 ampères may be used without inconvenience, the anode remaining untarnished. The electrolyte gradually absorbs carbon dioxide from the air, but this does not interfere with the working of the cell. It is, however, advisable to renew the electrolyte once each month.

Meeting held at Burlington House on December 6, 1920.

DR. CHARLES A. KEASE IN THE CHAIR.

THE DYESTUFF INDUSTRY.

BY HERBERT LEVINSTEIN.

The importation of dyes into this country was in fact controlled by Proclamation from February 25, 1919, until December 17, 1919, when Mr. Justice Sankey decided that the Order was invalid. On the very next day the President of the Board of Trade, Sir Auckland Geddes, stated in the House of Commons that legislation to secure the necessary powers to re-impose restrictions would be pressed forward in the next session.

It might therefore reasonably have been anticipated that this Bill would have been passed into law many months ago. In that case we should have been spared the disorganisation of the aniline dye industry which was caused by the large importation of German dyes during August, September, and October of this year, the necessity of throwing out of employment large numbers of workpeople engaged both in manufacturing and in new construction, and the feeling of uncertainty engendered in the minds of producers and consumers alike by the controversy which has recently arisen with regard to the Government policy.

The Government policy was announced in the House of Commons by Sir Albert Stanley as far back as May 15th, 1918, in these words, viz., "that the importation of all foreign dyestuffs shall be controlled by a system of licences for not less than ten years after the war, in order to safeguard this industry against the great efforts which the great German firms are certain to make after the war to destroy all we have accomplished during the war and to make this industry again subservient to Germany."

As Sir Albert Stanley was careful to state, the proposal was made on the advice of a Cabinet Committee of Mr. Asquith's Government and therefore had the approval of Mr. Asquith and his Government. It is now practically four years since Mr. Asquith's Government went out of office. Since then the proposals have been approved and the pledge given to the industry has been renewed by Mr. Lloyd George and his two Governments with the full knowledge and silent acquiescence of this Parliament and its predecessor.

It will be seen therefore that this is not a casual pledge thrown idly across the floor of the House by a Minister in a rash moment. There is no question of stampeding the House of Commons; but, on the contrary, great and regrettable delay has occurred in carrying out a policy which was agreed upon long ago by statesmen of very different political views.

The debate on the second reading of the Government Bill for controlling the importation of dyes, which takes place to-morrow, is therefore one of great importance, for if pledges solemnly made, and on the faith of which a great industry has been built up and millions of pounds spent, are not ratified by Parliament or become a matter for acute controversy, with the issue doubtful, nobody in the chemical industry will have the least confidence in Parliament.

Consider that it takes five years at a university for a young man to become a research chemist. He is then, or should be, a good organic chemist, but he is not a dyestuff chemist. It will be a further

two years before he is valuable as a dyestuff chemist for the purpose of research, and as a rule longer than that before he is useful on the manufacturing side. Our university chemical laboratories are filled with students at the present moment, a large number of whom have been attracted to this science by recognition at long last of the extraordinary importance of the dye industry and by the promise of the Government support. Years must elapse before the training of those who went to the universities after the Armistice is complete.

Those chemists who have been asked to do something which is vital to the State are entitled to say to Parliament and the public, "Having made up your mind that you want this industry, be consistent and do all that may be necessary to see it through. You want to attract our young men, the cream of our profession, and you can only do this by giving them an assured career."

I do not propose to deal with the merits of the Bill. I am solely concerned with the preservation of the industry. I am indifferent as to the means selected so long as they are adequate, but this I will say:—No alternative scheme likely to command support has been put forward. The Bill has the great merit in my eyes that it has the support of the great majority of dye users. That is very important. Further, it must be remembered that alternative schemes had been carefully considered by two Governments previous to this one, by four Presidents of the Board of Trade, and that the present Bill embodies the unanimous conclusion of many different men of great political sagacity and experience representing every grade of political thought of the House of Commons.

There is nothing in the assistance asked by the dye industry which brings it even remotely within the realms of party politics or of the acute political economic controversies of pre-war days; at any rate, it is supported by Mr. Asquith and Mr. Runciman, as well as by their successors and by such authorities as John Stuart Mill and Adam Smith. The former (*Political Economy*, Book IV, Chapter 10) says that the only case in which on mere principles of political economy protective duties can be defensible is when they are imposed temporarily in the hope of neutralising a foreign industry in itself perfectly suitable to the circumstances of the country. "Defence," says Adam Smith, "is of much more importance than opulence."

When I last addressed a meeting of the Society on the dye industry (in July, 1919; cf. J., 1919, 246 *r*) I gave four reasons why a large dye industry was vital to this country:—(1) It is a key industry. (2) It gives national security as a guarantee of peace. (3) The development of new industries is encouraged by organic research. (4) It is of political importance.

Key Industries.

As Lord Moulton said on December 8, 1914:—"We have had peace in England, and never thought of danger, industrial or national. Even though there may not be another war, there is perpetual war going on industrially. It is based on what, in the industrial world, corresponds to war in the political world."

In this industrial war, to use Lord Moulton's phrase, the struggle is for the control of the key industries, just as in political war, the struggle is for key positions, by the mastery of which dominance is secured over large tracts of enemy territory.

This point of view has been extremely well put by Mr. Vernon Clay, the Chairman of the Colour Users' Association, and is very clearly enunciated in the first instance by Mr. Runciman in a speech in the House of Commons which has been frequently quoted.

The German Interessen Gemeinschaft (I.G.) is making desperate attempts to recover the monopoly, because having once re-established it, they control our textile trade. They can refuse supplies, they can quote high prices to other countries, or they can use the advantage that they hold for the purpose of political bargaining. This is not a fanciful statement. I will give two instances:—

(1) Shortly after the armistice, the supply of dyes in Alsace became a question of difficulty to the French, and this difficulty was used by the Germans greatly to their political advantage. The great war development of our industry in England saved us during the Peace Conference from similar embarrassment. The Germans were unable in our case to use their predominance in the supply of dyes for bargaining purposes.

(2) The first practical method for the manufacture of Alizarin was patented almost simultaneously in Germany and in England in June of 1869. The English patentee was Perkin, the German patents were acquired by the Badische Co. Both patentees exchanged licences, so that Perkin obtained a monopoly for the manufacture of Alizarin in this country. In 1874 Perkin retired from business. His works were sold to Brook, Simpson, and Spiller, who in turn sold out later to Burt, Boulton, and Heywood. Perkin actually manufactured a ton of Alizarin Red in 1869, and in the following year he produced 40 tons, while the Germans only commenced manufacturing in 1871. In that year they produced 150 tons, while Perkin manufactured 220 tons. Two years later, viz., in 1873, the Germans already manufactured $2\frac{1}{2}$ times as much as Perkin, and a few years later they completely dominated the supply. This was due to the commercial enterprise of those directing the German factories, not to their superiority in science or large-scale manufacture. The German manufacturers themselves travelled, establishing agencies all over the world, while the British rested content with issuing circulars warning their customers against using inferior foreign-made goods. In this way by 1881 the Germans had secured so great a hold on the market that they combined together and formed the first Alizarine Convention with a view to raising prices. There was no Patent Law in Germany in those days. That is why there was more than one manufacturer in Germany. As a result, the Germans cleared £1,000,000 on this dye alone in one year. The next year, 1882, the year before the expiration of the patent, the Germans issued a famous circular in which they threatened to stop supplies to British consumers unless they agreed to extend their contracts at a fabulous price for 12 months after the expiration of the patent in 1883. The Scottish Turkey Red dyers replied to this coercive circular by going on to short time in order to conserve their stocks. They then formed a new company, a co-operative company to buy Messrs. Burt, Boulton, and Heywood's works. As a result, the first Alizarine Convention came to an end in 1885. Prices, which had been dropping ever since the formation of the British Alizarine Company, were then reduced to an unremunerative level. The extraordinary profits made by the German dye industry through the Alizarin monopoly enabled them to write off the cost of their works, to reconstruct them with huge laboratories, and to man them with skilled research chemists. At that time about one-third of the entire consumption of Alizarin was used in this country, so that these profits were made to a great extent out of the British consumer. In 1886, in an address to this Society, my father spoke as follows:—

"It is the development of the Alizarin industry in this country that our printers and dyers have to thank for a cheap and unlimited supply of Alizarin. It was the development of this new industry which the combination attempted to crush

in the germ, and this fact accounts for the present unremunerative price; and this endeavour on the part of some powerful continental colour-manufacturing companies to crush British competition by hook or by crook is not the only instance of such action. Now some may say that with all this reduction in the price of the article, our dyers and printers are not one iota better off to-day than they were when it was much higher. I would just invite such persons to consider what their position would have been if the combination had not been broken up. Turkey Red dyers, printers, and merchants, each and all of them, would have been at its mercy; and if it had so pleased the German combination, it might even have stopped our export trade in Turkey Red or Alizarin dyed goods by exacting prohibitive prices from our consumers, and thus diverted this important branch of the dyeing and printing trade into the hands of German manufacturers and merchants."

The expression "key industry" had not been invented, but already so early as 1881, it was clear that the manufacture of Alizarin Red was not one which could be safely left in the hands of a German trust. The manufacturers of dyes are now combined together in the I.G., which controls the manufacture not only of this important dye, but of every other dye. I need say no more on this point. Past history and past experience are surely sound guides to policy.

The formation of the British Alizarine Company saved the Turkey Red dyers. What was the result? The Germans first did all they could to put this company out of business, and finally in 1900 they made a Convention which included the British Alizarine Company. Under this Convention the British Alizarine Company was allowed to manufacture a certain quantity of Alizarin Red, and to sell it at a fixed price. This quantity was not a large quantity, but the sale was guaranteed. It was quite inadequate to supply the needs of this country and of the Empire, and when war broke out there was in consequence an acute shortage of Alizarin. The agreement entirely restricted development. The company just made the proportion of Alizarin which they were permitted to by the Germans, and sold it at the price fixed by the Germans. I say this because the position of the British Alizarine Company has been cited as an example of how aniline dyes can be made in this country in defiance of the Germans, and the business developed successfully in the face of competition. There were people who did develop their business in this country without making arrangements with the Germans, but their growth, like that of the British Alizarine Company, was restricted by the overwhelming competition which they met. The country is under a great debt to those energetic and able consumers who founded the British Alizarine Company when threatened by the German Alizarine Convention, and their action was, as far as I know, the first one taken by consumers to render themselves, if only in one dyestuff, not entirely dependent upon the German Convention.

National Security as a Guarantee to Peace.

The importance of the dye industry for national defence is, I think, now generally admitted. I see from an answer given by Mr. Churchill to Mr. Grattan Doyle on November 25 that the reports of the Commission which went to Germany early in 1919, and of Brigadier H. Hartley, may possibly be published in the near future. Of course, as Mr. Churchill admitted, the War Office is well aware of the fundamental part played by the German dyestuffs in keeping the German army in the field, but I will repeat that every toxic substance put in the field by the Germans during the war, with an insignificant exception, was made by the German Dyestuffs Trust, the I.G.. These substances were made by

methods devised by the I.G. in plant suitable for the manufacture of aniline dyes and of intermediate products. They contributed to the chemical warfare organisation of Germany:—

(1) Great, flexible plants suitable for making almost any organic substance on a large scale at a short notice.

(2) A highly-skilled personnel, capable of successfully conducting the large scale manufacture of complicated organic substances.

(3) A large research staff, experienced in making laboratory processes suitable for technical scale work.

It is said by some that the next war may not be a chemical war, but a bacteriological or a physical war. If we cannot produce a counter, the next war will certainly be a chemical war, and the results will be extraordinarily quick and decisive. Why was the last war in its later stages a chemical war? After the battle of the Marne the Germans selected chemistry as their most likely means of effecting a surprise because they were the sole belligerent possessing a large dyestuffs industry. Chemical warfare only failed to bring them a decision partly because they did not believe in their own weapon, and therefore were not prepared to follow up the results obtained, *e.g.*, the use of chlorine at the second battle of Ypres, and partly because they used their products on too narrow a front to secure a strategic result from the initial surprise, *e.g.*, the use of mustard gas.

All the belligerents would have used chemical means to effect their military objects on a more stupendous scale than was already the case in 1918 had the war dragged on to a further Spring campaign. Already at the end of 1918 70% of the casualties were caused by gas.

So long as there is no counter to the rapid production of toxic substances in Germany, the world is not safe; the menace of the Rhine factories lies, not only in their geographical position, but in the fact that they are unique.

That the next war will begin as a chemical war is certain, because it is an arm which has now been tried, the principles of which are well known to soldiers. Large appropriations have been made by Congress in America for carrying out chemical warfare research, and very drastic steps have been taken in the United States to safeguard their dye industry.

Research.

It is said by some people that the only thing necessary to enable the British dyestuffs industry to hold its own against the German I.G. is to give it sufficient money for research. There is no stronger protagonist of research than I am, but it is my opinion that the mere endowment of laboratory research—and this I presume is meant—would not lead to any practical results. The creation of a great industry from a laboratory reaction or invention is not an automatic process. Organised industrial research can only be successfully carried out—and spasmodic research is of no importance—by great organisations willing to devote sums of money not only to employing a large scientific staff, but for experimental work on a large or semi-large scale, and to erect great factories. This presupposes a great industrial organisation with technical experience and a commercial organisation of sufficient insight and imagination, extending over the markets of the world.

The cost of the laboratory work is a comparatively small charge in the development of a new industry. To endow laboratory research for industrial purposes, unless the conditions for large-scale exploitation exist, would seem a curious procedure. What

does the inventor of a new laboratory reaction do if he has no such organisation behind him and if he is not backed by a large manufacturing concern able to assist in its technical development on the large scale? He can only sell his invention to those who have. What is required for this technical development? A staff of experienced technologists, a plant design section, a constructional engineering section, and, above all, the money to carry out the work on a large scale. The laboratory chemist is a pure research chemist and has, in my experience, neither the knowledge nor the desire for large-scale work. The qualities which make for success in these two branches are different and seldom combined in one person.

Thus the process of fixing atmospheric nitrogen in the form of ammonia was in a sense invented by Professor Haber, but its technical development was entirely due to the Badische Co., and its commercial value is enormously enhanced by the fact that it is exploited by a dye trust. Could Haber have developed this invention himself without the aid of the Badische Co.? The process should really be called the Haber-Bosch, not the Haber process. The first Badische synthetic Indigo was not discovered at Ludwigshafen, but by Henmann, professor of chemistry at Zürich. Could Henmann have developed his invention? The reaction was technically valueless and only became a commercial success after a great deal of money had been spent upon it by the able technologists of the Badische Co.

There are numerous other examples, *e.g.*, incandescence mantles, argon and the 3-watt lamp, helium and airships. The ammonia-soda process was patented by Dyar and Henning in 1838; yet it was only in 1865 that Ernest Solvay, the creator of the industry, was able to start a works near Charleroi. Even after Solvay had shown the way in 1873, Ludwig Mond, a man of outstanding talent, who obtained a licence from Solvay, risked all the capital that he and his partner had at Northwich, and only after incredible anxiety, assiduity, experimentation and failure the great firm of Brunner Mond emerged successfully.

Did the discovery of viscose by Cross and Bevan create the artificial silk industry which Messrs. Courtaulds now dominate? Everyone knows that that is not so.

We have to-day magnificent research organisations, directed by some of the most brilliant and original minds in the country, staffed by the best young chemists obtainable. We spent on these organisations, exclusive of capital, over £100,000 last year; we employed last year 100 academically trained research chemists. Could we have spent more? I think not at this stage of our development. We hope in due course to employ far more and to spend greater sums on research. But the development of research must be proportionate to the capacity of the factory organisation for making a profitable use of scientific work, just as the development which the factory can undergo is purely a function of the success of the commercial organisation in promoting sales. That is the essence, the vital point is harnessing science, industry, and commerce.

Conclusion.

If we desire our textile trades to flourish, unhampered by conditions or restrictions imposed upon them by a foreign trust; if we desire to carry on our lives peacefully, without a constant menace from these great factories on the Rhine, potential arsenals; if we desire to train our young men in the pursuit of chemistry to organise progress in the inventive industries, and not merely to rely on our staple industries while other nations more progressive launch out into the unknown; if we desire

these things, or any one of them, we will, as a nation, take any measures which may be necessary now and during the next few years to establish the coal tar colour industry in this country.

DISCUSSION.

SIR WILLIAM PEARCE, M.P., said that he had been a member of Lord Balfour of Burleigh's Committee, which nearly five years ago had first made the recommendation that key industries should be supported at any risk and at any cost; that had been the beginning of Government policy. One of the difficulties of the present Bill was that in the few years before the war the textile industry in this country had been treated by the Germans with the greatest consideration. The industry had not only had the most favoured clause with regard to prices but he believed dyes had been sold in this country to the textile industry at prices lower than in Germany or any other country in the world. Moreover, the big German organisations had sent their agents over here to give full information with regard to the application of a colour. The prices of German dyes having been so low, it had been no encouragement for anyone to embark on the dye industry here on a large scale without Government help. Dr. Levinstein had made one very good point as to how the textile industry, if it went back to these conditions, might find itself some day with its supply of dyes refused in the interests of the German textile industry, but even apart from that, there was something national at the back of the German dye industry. In 1913 the Germans had made 100,000 tons of ammonia from atmospheric nitrogen at a cost of roughly £5 per ton, and in 1914 the whole of that had been placed on the European market at £11 per ton. The Germans had known that if they went into a world war their stocks of sodium nitrate would soon have been exhausted, and they could not have carried on for two years but for the Haber process. What had been our position compared with Germany when the war broke out? The first thing that had come into prominence in the war had been anhydrous sulphuric acid. The total demand for anhydrous sulphuric acid in this country before the war had been under 500 tons per week, but the Germans had been producing 10,000 tons a week and possibly more. Directly we had come to manufacture nitroglycerin or gun-cotton or T.N.T. in large quantities we in this country had been in the greatest distress owing to the lack of sufficiently large plant. In regard to high explosives, we had again been met with the fact that there had been not only insufficient oleum, but no manufacture of T.N.T. on any scale at all in this country. At the time the present Prime Minister had stated from the Front Bench that, thanks to Lord Moulton, we had secured an ample supply of high explosives for ourselves and our allies, there was not 20 tons of T.N.T. per week being made in this country. Our requirements at the end of the war had been about 2000 tons. In the same way there had been at that time no plant in this country capable of producing a large quantity of chlorine, or even of hydrogen. He believed we had nearly lost the war because we had no mustard gas shells. The risk we ran had been frightful. Who could say that the same thing would not happen again if we did not possess a large organic and synthetic chemical industry in this country? It was necessary in the interests of this country, from the peace point of view, quite apart from the possibilities of war, that this industry should be allowed to establish itself. It was imperative that the Government should pass this Bill in the interests of the nation.

PROF. H. E. ARMSTRONG said he hoped that a copy of Dr. Levinstein's address would be sent to

every member of the House of Commons. It was unfortunate that it had not been delivered in time to produce an effect in connexion with the second reading of the Bill, because he could not imagine anything more likely to lead to a sweeping vote in favour of it. On the whole, they would be inclined to agree with Dr. Levinstein that research, after all, was no good if carried out merely from the academic point of view; that it had to be put into practice to make it of value. At the same time, he felt that Dr. Levinstein had, he was sure unconsciously, very much under-rated the value of ideas. The whole trend of late years had been very much in the direction of carrying out research work for the sake of the money to be made out of it. We should be raising the wrong type of man if we put that view forward, as had been the case lately. Over and over again he himself had expressed the view that the failure in this country was a commercial failure, due to lack of commercial insight, lack of breadth of outlook, on the commercial side, and that was one of the points which ought to be brought before the House. If there had not been this entire lack of foresight on the part of members of the House as a whole we should not be in the parlous position we were to-day, because they had not been sufficiently informed to appreciate the value of science. It was the very fact that the Germans had had this foresight that had given them their pre-eminence. There was no better evidence of this than the fact that the Badische Company had offered Dr. Emil Fischer £5000 a year when he, a young and unknown man, had discovered the nature of Rosaniline. Dr. Levinstein's main argument was a sound one, that this country was bound to fail if it did not develop the particular type of industry which he represented, but the subject must be looked at from a very much broader point of view than that which Dr. Levinstein had put before them. If we were to develop our agricultural resources and intensive culture to the necessary extent to meet the requirements of our growing population it would be through the agency of the organic chemist, and we must convince our legislators of the absolute need to develop this particular industry and of the importance of organic chemists for its progress.

MR. F. H. CARR agreed as to the vital importance of the organic chemical industry to this country, but pointed out that it was not alone the dye industry or that part of applied organic chemistry that was concerned with the next war, but the development of biochemistry, the advance of our knowledge of the vital elements for the preservation of life and for the destruction of life; that was the type of work which was bound to develop, that branch of our industry which was concerned with the production of drugs and chemicals of that type. It was for that reason he was convinced that it was of vital importance that not only the dye industry, but the whole of the organic chemical industry should be preserved in the interests of peace as well as war. With reference to what Prof. Armstrong had said as to the value of ideas, he had not understood Dr. Levinstein to speak disparagingly of the value of ideas at all, but rather to the effect that ideas, even with a well-paid chemical staff, cost less in money and less in patience than did the technical scale experiments, which required not merely large sums of money and good chemists, but large sums of money for workers on the engineering side, and so forth. He alluded to this because the British Dyestuffs Corporation and other dyestuffs companies which were operating in this country at the present time had not had the least chance of establishing their industry. Even if, during the few years they had been at work, they had had full opportunities, the time would not have been sufficient to put them in a position to

compete openly with an industry so highly developed as it was in Germany, but these companies had been working under war conditions and had not had anything like the proper opportunities. Therefore, not only must we expect to spend a lot of money on the technical scale experiments, but we must expect to exercise great patience in seeing a lot of mistakes made, and it was only by overcoming these mistakes that ultimate success would be obtained.

MR. R. WADDINGTON, M.P., said that he, together with many of his colleagues in the House of Commons, was satisfied that the Bill which had been presented by the Government was the best solution of the problem and would give the greatest satisfaction to the textile users, and at the same time be the best means of building up the dye industry in this country.

SIR CLEMENT KINLOCH COOKE, M.P., said that he personally was in favour of the Bill, and several other members of the House of Commons who had spoken to him on the subject were all agreed that the Bill was a good one and that they would support it. He had no doubt whatever that the second reading would be passed by a large majority.

DR. M. O. FORSTER said that Prof. Armstrong had referred to the question of commercial incentive to organic research. On that point he agreed with Mr. Carr's remarks. He had not understood Dr. Levinstein to say anything diminishing in any sense whatever the importance of ideas. What Dr. Levinstein had done was to emphasise the need of incentive to research; he regarded that as of tremendous importance. His own view was that a subsidy for the dye industry on the scale which would be required, i.e., a scale which would practically maintain the industry whilst it was not selling any goods at all, was impossible. He could not imagine anything more demoralising to the staff of the Corporation from the scientific standpoint than such a situation, because, delighted as they all were to do what was called pure research, and splendid as it was as a mental development, nevertheless, it was an incentive to these workers to think that they might hope that something useful would arise from what they were doing. If they went on year after year seeing nothing useful arise from what they did in the laboratory, if they merely saw their records filed and no goods sold, he could not imagine that any more young men would be inclined to go in for the study of organic chemistry. In his opinion the dye industry was not really a key industry, but merely a branch of the textile industry. Had the textile manufacturers fifty years ago taken that much broader view of the dye industry, and subsidised it by setting aside a percentage of their profits, they would have enabled an industry to be built up in this country just as it had been built up in Germany.

MR. REGINALD B. BROWN said that the correspondence, not only in *The Times* of London, but also in *The Manchester Guardian* during the last fortnight or so, had shown a most remarkable diversity of opinion as to the advisability of the measure now being brought forward and as to the precise terms of the Bill which would meet with the fullest support. One argument which was certain to be advanced, but which, perhaps, had not been considered sufficiently that evening, was that if we could not get constant supplies of German colours our textile industries here would suffer severely, and therefore we should suffer in competition in foreign markets. That was probably an argument of which the most would be made in the House of Commons. He believed he was correct in saying that the strongest opposition would come from the Calico Printers' Association, which represented users

of specially fast dyestuffs which were not yet produced in this country. Whilst that was to some extent correct, it was necessary to point out that the Bill did not entirely prohibit the importation of these special German dyestuffs at present, but merely said that they were to be imported under licence, and that if the Committee, which consisted of a majority of colour users, could prove to the satisfaction of the Board of Trade that these colours were necessary for their particular industry and were not being produced in sufficient quantity or of a sufficiently good quality in this country, then they could be imported. As Dr. Levinstein had said, there were vast numbers of chemists being trained in the colleges in this country, and it might reasonably be hoped that the industry, given a few years in which to build itself up, would, with the aid of these young chemists, be brought into such a position and gain such experience on the commercial side that all the needs of this country could be met. It was necessary to build up the industry by the co-operation of science, technology, and commerce, and only in that way would it be possible for the full range of colours required by the textile industry to be made available. He did not believe in the argument that the Germans would refuse to sell colours if the Bill went through, but he did believe that they would do all they could to kill the dye industry in this country if the Bill was not passed. He did not agree with Dr. Forster that the dye industry was a branch of the textile industry. It was much wider than that, because it touched many trades, such as the leather trade, the paint trade, the paper trade, and others which strictly would not be called textile industries. As an industry itself, the dye industry was of the greatest importance for our national industries and national life, and he hoped that those Members of Parliament who were present that evening would be convinced of the urgency of the Bill and be strengthened in their conviction of the necessity for it.

DR. STEPHEN MIALl strongly deprecated the manner in which this matter had been left until the very last minute. Owing to the disgraceful management of this business by successive Governments during the last few years, the country had been brought to such an extraordinarily dangerous position. It was far more serious than had been indicated in the discussion. The trade had now got into a state that only the very promptest measures could save it from absolute extinction.

MR. WALTER F. REID recalled the important part which Dr. Levinstein's father had played, not only in developing the dye industry in this country, but also in fighting the German monopoly and in regard to patents. Patents had been the means of controlling the German interests in this country and fighting the British. Mr. Ivan Levinstein had been a member of a deputation to the Board of Trade at the time Mr. Lloyd George had been President, and he (Mr. Reid) had represented the Society of Chemical Industry on that occasion. One of the points brought before Mr. Lloyd George had been that the fixation of nitrogen from the atmosphere was then being developed abroad, and that if it was not established in this country before the outbreak of a war we should find ourselves in a very awkward position. Mr. Lloyd George had at once asked for a small committee to be nominated to confer with him on the matter. The result of that had been the introduction of the compulsory working of patents in this country. That had had one small effect, that the Germans had erected a model factory in this country. Nevertheless, it had had some practical effect, but the Courts of Law had given a decision which rendered this absolutely useless in the same way as a recent judgment had done in regard to licences for importation. Chemists

ought to take some steps to see that the regulations that were passed and the advice given to the Government by the law officers was advice that was really of some use. With regard to research, he quite agreed that research alone was of little use; it was only those who were in actual contact with industry and who had the means of utilising the raw material who could put it to proper use. An inventive head was required, and this was a matter which should be thoroughly considered in the agitation for large sums to be spent on research work.

Mr. W. MACNAB said that a great deal had been made of the fact that in spite of our unpreparedness we had won the war. That was perfectly true, but it was not realised that the cost in money of the improvisation that had to be resorted to and in the suffering had been caused by our lack of preparedness. That was an aspect which should not be overlooked in regard to the future.

Mr. W. J. U. WOOLCOCK, M.P., said that it must not be imagined that the Government's Bill was purely and simply one for the prohibition of the import of foreign dyes into this country: it was a Bill for the establishment of a dye industry in this country. It was not proposed to prohibit straight away the whole importation of German dyes into this country without any consideration for the textile manufacturers; neither were they asking, as dye makers, for protection which would give no spur whatever to progress in the industry. On the contrary, the dye makers said that if they had the Bill they were prepared that the policy of the Licensing Committee should be to ask the British dye maker to demonstrate that he could produce the dyes required before there was any thought of cutting off the necessary supplies. That, to his mind, was one of the best features of the proposals, and he personally would never be a supporter of any protection for any industry which would cause that industry to go to seed and rest on protection. Such a course would not establish a dye industry in this country.

Mr. E. V. EVANS said that it was impossible under the present conditions to stand up against the form of competition that Germany was able to provide at the moment, and would be even more able to do in the future, unless some form of legislation were brought in to deal with it.

Dr. LEVINSTEIN, in reply, said that the degree of unanimity which had been shown with regard to the paper was greater than was usually obtained in a meeting of chemists. They were fortunate in having Sir William Pearce as their protagonist in the House of Commons for the Bill, and he had every hope that the result in the House of Commons would be as unanimous as the present meeting.

Communications.

THE DYEING OF ARTIFICIAL SILK.*

BY THE LATE LEONARD PHILIP WILSON AND MARJORIE IMISON.

The dyeing of artificial silk has, as a rule, been considered to be practically identical with the dyeing of cotton, but since it has a greater affinity for dyestuffs, and unevenness in shade is occasion-

ally observed in the dyed material, it was thought desirable to investigate the dyeing of viscose artificial silk from a fresh standpoint.

It has hitherto been assumed that all direct cotton colours are as suitable for use with artificial silk as with cotton, but recent research has clearly shown that only a limited number can be considered to be eminently suitable from the point of view of giving even effects. The reason for this is that many of these colours are extremely sensitive to those small differences of dyeing affinity which are at present liable to occur occasionally in artificial silk, as indeed they do in all textile fibres, but which in the case of short fibres, such as cotton and wool, are concealed by the mixing of a very large number of fibres to form a thread.

Among the sulphur colours also there are many which are very sensitive to variations in the affinity for dyes of the artificial silk fibres, but fortunately the "even" or less sensitive colours of this class include shades which help to fill in the gaps in the range of "even" direct cotton colours. By the term "even" as applied to dyestuffs in this connexion is meant the property of the dyestuff of giving an equal depth of colour on artificial silk fibres of different affinities.

Tannic acid, which is used as a mordant for basic dyestuffs, is taken up by the thread like a dyestuff and behaves to a certain extent in the objectionable manner of many of the direct cotton and sulphur colours; thus, if there are irregularities in the artificial silk, the basic colours when used with a tannic acid mordant may give uneven results. Where they are used for topping other dyestuffs, the final result is dependent upon the effect obtained with the bottom colour.

Sky Blue F.F. is one of the dyes which is frequently connected with complaints of uneven dyeing, but recent research has shown that if there are some conspicuous offenders in this respect, there are others, e.g., Chrysophenine G., of which no complaint can reasonably be made since they consistently give even shades when used in the orthodox manner.

Methods have been devised which serve to measure the extent to which a dyestuff can exhibit unevenness. A large number of dyes have been tested and, according to the degree of evenness which they show with fibres of known different affinities, when dyed under standard conditions, have been classified as "even," "moderately even," and "uneven."

No superiority in respect of evenness can be claimed for the products of the German dyeworks. A given dyestuff, whether it be labelled Diamine, Oxamine, Dianol, or Paramine, will be classed as "even" or "uneven" (as the case may be) according to its constitution and behaviour, which are independent of its German or British prefix. For example, Diamine Sky Blue F.F. (Cassella), Chlorazol Sky Blue F.F. (Brit. Dyestuffs Corp.), and Chloramine Sky Blue F.F. (Sandoz) are all "uneven," as are also Diamine Black B.H. (Cassella), Oxamine Black B.H. (Badische), Melantherine B.H. (Soc. Chem. Ind. Basle), Melantherine B.H. (Clayton Aniline), and Chloramine Black B.H. (Sandoz). On the other hand, Sultan Yellow G. (Brit. Dyestuffs Corp.) and Chrysophenine G. (various makers) are "even," while Cotton Red 4 B. (Soc. Chim. Ind. Basle), Benzopurpurin 4 B. (Sandoz), Benzopurpurin 4 B. (Brit. Dyestuffs Corp.), and Diamine Red 4 B. (Cassella) are "moderately even."

It has been found, however, that evenness (at normal dyeing temperature, 50° C.) varies according to the molecular weight of the dyestuff used;

* The reading of this paper at the meeting of the Birmingham Section on October 21st was cancelled owing to the sudden death of Mr. Wilson on October 16th.

the arrangement of the groups in the molecule and their nature have, apparently, no real effect. The dyestuffs of low molecular weight give very even results under normal dyeing conditions, although the silks may vary considerably; while with the same irregular silks the dyestuffs of high molecular weight give uneven results. For example, Rosophenine 10 B. (mol. wt. 600) is even dyeing, whereas Dianol Sky Blue (mol. wt. 992) is very uneven; Indoine Blue (mol. wt. approx. 521) is very even, but Dianol Fast Pink B.K. (mol. wt. 944) again is very uneven; Diamine Green B. (mol. wt. 812) is fairly uneven, and so on. The result is that fabric made up of artificial silk of varying affinities will show variations in shade when dyed with dyestuffs of high mol. wt. and a practically even effect if dyestuffs of low mol. wt. are employed.

The lists given below show the direct cotton colours which have been tested classified as those showing good evenness, those of moderate evenness, and the uneven ones, determinations having been made by dyeing at 50° C. The lists may include the same dyestuff under more than one name and must, for the present, be regarded as provisional and subject to alteration as research proceeds. A large number of German dyes which have been tested are not included.

EVEN DYES (DIRECT COTTON COLOURS).

Red.—Chlorazol Red A., Chlorazol Pink R.D., Chlorazol Fast Bordeaux B., Dianol Fast Red K., Dianol Fast Red F.G., Congo Corinth G.W., Congo Rubine (all British Dyestuffs Corporation), Chloramine Red B., Chloramine Fast Red F. (Sandoz), Rosophenine 10 B. (Clayton Aniline), Rosanthrene B., Rosanthrene R., Rosanthrene Bordeaux B., Cotton Red C. (Soc. Chem. Ind. Basle).

Brown.—Chlorazol Brown G.R. and Dianol Brown G.M. (British Dyestuffs Corp.), Trisulphon Brown M.B. and Chloramine Brown 2 R. (Sandoz), Cupranil Brown B. and Chlorantine Pure Brown 3 G.L. (S.C.I. Basle).

Orange.—Congo Orange R. (British Dyestuffs Corp.), Paramine Direct Orange R. (Holliday).

Yellow.—Chrysophenine G. (Sandoz), Sultan Yellow G. (British Dyestuffs Corp.), Cotton Yellow C.H. (S.C.I. Basle).

Blue.—Indoine Blue (Badische: this colour dyes artificial silk without a mordant).

Violet.—Chlorazol Violet W.B. (British Dyestuffs Corp.), Direct Violet 2 B. (S.C.I. Basle).

MODERATELY EVEN DYES.

Red.—Brilliant Congo Red R. (Sandoz).

Brown.—Paramine Direct Brown G. (Holliday), Dianol Brown 2494 (British Dyestuffs Corp.).

Orange.—Stilbene Orange J R. (Clayton Aniline).

Yellow.—Titan Yellow G. (British Dyestuffs Corp.).

Green.—Dianol Dark Green N. (British Dyestuffs Corp.).

Violet.—Direct Violet 2 R. (S.C.I. Basle).

Black.—Vulcan Black 2 G.W. (British Dyestuffs Corp.), Direct Fast Black B. (S.C.I. Basle).

UNEVEN DYES (DIRECT COTTON COLOURS).

Red.—Direct Fast Scarlet S.E. (S.C.I. Basle), Chloramine Brill. Red 8 B (Sandoz), Dianol Fast Pink B.K. (Brit. Dyestuffs Corp.).

Brown.—Trisulphon Brown B. and Trisulphon Bronze B. (Sandoz), Cupranil Brown G. (S.C.I. Basle).

Orange.—Pyrazole Orange G. (Sandoz).

Yellow.—Dianol Fast Yellow A.R.X. and Afghan Yellow G.X. (Brit. Dyestuffs Corp.), Paramine Direct Yellow R. (Holliday), Oxypheanine R. and Oxypheanine G.G. (Clayton Aniline).

Green.—Dianol Green B.G. (Brit. Dyestuffs Corp.), Direct Green G. and Direct Green B. (Sandoz), Direct Green B. (Clayton Aniline).

Blue.—Sky Blue F.F., Dark Blue B., Blue 2 B., Fast Blue G. (all makers), and many others.

Violet.—Trisulphon Violet B. (Sandoz), Direct Violet R. (Clayton Aniline), Chlorazol Violet B.N., Dianol Violet R. 9068 K., and Dianol Violet R. (Brit. Dyestuffs Corp.), Direct Violet N. (S.C.I. Basle).

Black.—Black B.H. (all makers), Chlorazol Black E. Extra and Dianol Black No. 1 (Brit. Dyestuffs Corp.), Chloramine Black H.W. and Chloramine Black E.X. Extra (Sandoz), Melantherine T.H. and Indigene Black B.W. (S.C.I. Basle).

From these lists it is apparent that there are many direct cotton dyestuffs which, when employed in the usual manner, will give unsatisfactory results if there is any unevenness in the artificial silk, but, on the other hand, a considerable number will give good and even shades in most colours. The work of investigation into the evenness of dyestuffs is still in progress, but up to the present only one or two satisfactory direct blues have been found, and for most blue shades other methods must be adopted to ensure more even results. It may, however, be possible now that the test of evenness has been ascertained, for manufacturers to produce blue dyestuffs of low molecular weight, and investigations have been started with this end in view.

It has been found, moreover, that it is possible by dyeing at other temperatures to obtain more even results with dyestuffs which, when tested at 50° C., were classified as uneven. With higher temperatures of the dyebath, the amounts of dye absorbed by two silks of very different affinities gradually approach one another, so that whereas when dyed at 35° C. one silk might be six times as dark as the other, when dyed at 75° C. there is very little difference between them; the silks, of course, were immersed in the bath at the proper high temperature and not put into a cool bath and subsequently heated.

When using mixtures of direct cotton dyestuffs, even results can only be obtained if all the dyestuffs in the mixture are even; a dyebath composed of both even and uneven dyes almost invariably gives worse results than the uneven dyes alone. It has also been found that when material dyed with an uneven dye and showing variation in shade is bleached and afterwards re-dyed with an even dye, the final result will frequently be uneven.

It has already been stated that some of the sulphur colours will help to supply the deficiencies in the direct colours. The sulphur dyes as a class cannot, however, be said to give even results, as many of them do not, but it is fortunate that among the blue sulphur colours some have been found which give even shades on artificial silk of varying affinity. It is possible, therefore, by the use of these to extend considerably the range of colours which do not show unevenness, and the following dyestuffs can be recommended to this end.

EVEN DYESTUFFS (SULPHUR COLOURS).

Thionol Sky Blue P.X. (Brit. Dyestuffs Corp.), Pyrogene Direct Blue R.L., Pyrogene Direct Blue (green shade), and Pyrogene Indigo (S.C.I. Basle), Thionone Brilliant Blue G. and Thionone Navy Blue B. (Holliday).

The sulphur colours named below have been found to give uneven results:—

UNEVEN DYES (SULPHUR COLOURS).

Blue.—Thionol Navy Blue R., Thionol Navy Blue 9055 K., Thionol Direct Blue S. (Brit. Dyestuffs Corp.), Thional Dark Blue S. and Thional Dark Blue R.L. (Sandoz), Thionone Indigo R. and Thionone Navy Blue 2 R. (Holliday).

Black.—Thionol Black O.G., Thionol Black XXN Conc., and Thionol Black S.G.G. (Brit. Dyestuffs Corp.), Thionone Black Paste (Holliday).

The basic colours find considerable application on artificial silk where great fastness in the dyed silk is not essential. In addition to producing extremely bright shades, basic dyes as a class possesses the great advantage of giving the most even dyeing results. In fact, almost without exception, these colours can be made to give shades which show no sign of unevenness when used to dye artificial silks of very different affinities. It should be noted that these dyes are of low molecular weight.

With the usual method of dyeing, *i.e.*, with a preliminary mordanting with tannic acid and tartar emetic, unevenness may, as stated above, sometimes result when the material is dyed, but to a much smaller extent than with many of the direct colours. The most even results are to be obtained by dyeing first in a neutral dyebath, and then fixing in tannic acid and tartar emetic.

The fact that basic colours are, on the whole, even dyeing, enhances their value for topping direct or sulphur colours and extends the range of shades which can be produced, and which might be curtailed by the reduction in the number of dyes available if only those which fulfil the requirements of even dyeing are to be used.

It has thus been found that, among all classes of dyestuffs investigated, there are some which under normal conditions of dyeing exhibit great sensitiveness to variations in artificial silk, and special methods have been indicated for dyeing with some of these colours which tend to make them less sensitive. On the other hand, there are many dyes of undoubted even-dyeing properties covering, in one class or another, a full range of colours; and it is hoped that the extended use of these and the restricted or more careful use of uneven colours will tend further to eliminate irregularities in dyed viscose silk.

A CONTRIBUTION TO THE THEORY OF POLYMERISATION IN FATTY OILS.

BY ARTHUR H. SALWAY, D.S.C., PH.D.

The phenomenon of polymerisation is best observed with highly unsaturated oils, notably Chinese wood oil (tung oil) and linseed oil, but is not

Polymerisation of an oil is accompanied by an increase in the density, viscosity, refractive index,* and mean molecular weight of the oil, and a decrease in the iodine absorption. The melting point of the total fatty acids is raised slightly by polymerisation, whilst the proportion of free fatty acid is also increased to some extent (Wolff, *Farbenzeit.*, 1913, 18, 1171). Furthermore, it is stated that the glyceryl radicle remains unchanged during polymerisation, whilst the saponification value of the oil is not materially affected.

Several attempts have been made from time to time to explain the physical and chemical changes attending the process of polymerisation (*e.g.*, Kronstein, *Ber.*, 1902, 35, 4153; Kitt, *Chem. Rev. Fett- u. Harz-Ind.*, 1905, 12, 241; Normann, *Chem.-Zeit.*, 1907, 188; Wolff, *loc. cit.*; Morrell, *J.*, 1915, 105; Fahrion, *Chem. Umschau*, 1917, 24, 103), but none of the theories so far advanced can be considered to provide an entirely satisfactory explanation of the change. Hitherto it has generally been considered that the unsaturated fatty acid radicle in the fatty oil is the seat of the polymerisation. Morrell (*J.*, 1918, 181) has, however, recently shown that the fatty acids (or methyl esters) obtained from polymerised tung oil are of normal molecular weight, from which it may be concluded that depolymerisation occurs with surprising ease, or that polymerisation is not entirely conditioned by the unsaturated acids. In fact, it seems necessary, for a satisfactory explanation of the observed experimental data, to assume that the glyceryl radicle is also involved in the polymerisation. It is stated, however (Lewkowitsch, *J.*, 1903, 592), that the glycerol is unaltered during polymerisation, although Kitt (*loc. cit.*) observed that an apparent loss of glycerol occurred in polymerising linseed oil. Kitt attached no special theoretical significance to this result, for, according to his theory, polymerisation of fatty oils consists first in the production of free fatty acids, which then condense with the production of inner anhydrides or lactenes.

There is much to be said for this view, especially if it be so modified to include a change in the glyceryl radicle. For this reason the author advances the suggestion that the mechanism of the process is as follows:—At the high temperature necessary for polymerisation, there is first a liberation of one or more fatty acid radicles, which then condense with the unsaturated linkages of the fatty oil. This condensation takes place between the free acidic groups on the one hand and the unsaturated linkages of fat on the other hand, and the result is a partial saturation of the fat. This change may in general be represented as shown below†.

It will be seen that as a result of the reaction formulated above, one glyceryl hydroxyl group becomes free. At the high temperature required for polymerisation, however, such a compound might be expected to condense with the formation of a polyglycerol derivative as represented below, thus accounting for the increased weight of a polymerised oil.

According to this view, polymerisation consists in an internal rearrangement of fatty acid radicles

entirely peculiar to highly unsaturated oils, for most fatty oils can be made to undergo the change to a greater or less extent. For example, olive, arachis and cottonseed oils contain a considerable proportion of glyceride which gelatinises like tung oil if the non-polymerisable portion of the oil is removed by distillation (Kronstein, *Ber.*, 1916, 49, 722).

* A decrease in refractive index sometimes occurs when tung oil is polymerised.

† These formulae must not be regarded as representing the exact change of any particular oil; they are only intended to indicate the way in which the unsaturated linkages and a fatty acid radicle are involved in the process. The change is not necessarily limited to one fatty acid radicle and one unsaturated linkage; numerous combinations are possible.

involving a partial saturation of the molecule and the production of a polyglycerol fat. A change of such a character accounts satisfactorily for the observed increase in molecular weight, density, and viscosity of the oil, as well as the decrease in iodine value. It would explain why polymerised oils have substantially the same saponification value before and after polymerisation and why the fatty acids

from a polymerised oil have a normal molecular weight. The two main reactions which occur during polymerisation of oils according to this theory are (a) the union of a carboxylic group of a fatty acid with an unsaturated linkage or series of unsaturated linkages, and (b) the condensation of a so-called diglyceride with the formation of a polyglyceride.

With regard to the first reaction, it is well known that unsaturated fatty acids readily combine with sulphuric acid, with the formation of sulphuric esters according to the following scheme:—

A similar reaction undoubtedly occurs when a highly unsaturated fatty acid is heated alone (Fahrión, *Farben-Zeit.*, 1913, 18, 2111), for in this case, instead of the sulphuric acid, a second molecule of the fatty acid is involved in the condensation, an O.CO.R group taking the place of the O.SO₃H in the above scheme. The result is a reduction both in iodine value and acid value.

Experimental evidence in support of this conclusion was obtained by heating fatty acids from linseed oil and palm oil separately at 270° C. for 6 hours in the presence of carbon dioxide and then observing the change in iodine and acid values of the fatty acids. The results were:—

		Linseed oil fatty acids.	Palm oil fatty acids.
Iodine value	Before polymerisation	200.7	55
	After	176.9	54.5
Acid value	Before	191.5	199
	After	181.1	198
Sap. value	Before	196.1	200
	After	198.5	201

It is clear from these figures that in the case of the linseed oil fatty acids, a reduction in iodine value is accompanied by a reduction in acid value, whilst with the comparatively saturated acids of palm oil there is no appreciable reduction either in iodine value or acid value. This is a fact of some significance from which it may be concluded that the reduction of acidity is not due to anhydride formation, R.CO.OH + (R.CO)₂O, but is correlated with the reduction of iodine value and brought about in the manner formulated above.

Since fatty acids are thus shown to be capable of combining with highly unsaturated linkages, it is only reasonable to conclude that a similar reaction would occur between a fatty acid and an unsaturated glyceride in the manner suggested above in the first stage of the polymerisation of fatty oils. The free fatty acid required for that reaction

may be originally present in the fat or it may be produced during polymerisation. There is, indeed, reason to believe that all fats when heated to the usual polymerisation temperature undergo a kind of dissociation with the liberation of fatty acid, for it is precisely at this temperature, 250°–270° C., that heated fats begin to evolve visible amounts of volatile substances. Kronstein's observation that

olive oil, arachis oil, cotton seed oil, etc., are polymerised when distilled is of interest in this connection (cf. Kraft, *Ber.*, 1903, 36, 4343, and Bömer and Baumann, *Z. Unters. Nahr. Genussm.*, 1920, 40, 97, on the temperature of decomposition of fats when distilled in a high vacuum).

If this view of the first stage in the polymerisation is correct the introduction of free fatty acid should accelerate the reduction in iodine value. On the other hand, if the formation of free fatty is retarded by any means, the reduction in iodine value on heating should also be retarded. That this is actually the case is shown by polymerising whale oil in the presence of an excess of fatty acid on the one hand, and in the presence of an excess of glycerin on the other hand. In the former case, the rate of reduction of iodine value was found to be accelerated; in the latter case retarded. In the experiments to demonstrate this fact, a sample of crude whale oil was refined by means of caustic soda and fuller's earth, after which the oil was washed and dried at 100° C. under diminished pressure. For the polymerisation, samples of the oil were heated for 8 hours at 250°–270° C. in sealed tubes in the presence of carbon dioxide. The tubes were heated side by side in an oil bath under identical conditions. Two series of experiments were made, in one of which known amounts of fatty acid from whale oil were added before polymerising, whilst in the other series glycerin was added in known amounts. The results of the experiments were:—

Effect of free fatty acid.

		Before treatment.	Iodine value. After treatment.
Whale oil (neutral)	..	121	106.8
	.. + 1% F.A.	121	100.5
	.. + 2% F.A.	121	99.8
	.. + 3% F.A.	121	97.6

Effect of glycerin.

		Before treatment.	Iodine value. After treatment.	Reduction %
Whale oil (neutral)	..	121	94.8	21.8
	.. + 10% glycerin	110	93.6	15.1
	.. + 20% ..	101	89.9	11.0

It is thus evident that the reduction of iodine value is accelerated by the addition of free fatty acid and retarded by the addition of glycerin.

Passing on to the second stage of the above theory of polymerisation, namely, the stage involving a condensation of the glyceryl radicle, the evidence is less convincing. According to this view the glycerol obtained from a polymerised oil should contain polyglycerol, but no direct evidence has yet been obtained that this is the case. It is, however, well known that glycerides containing free glyceryl hydroxyl groups (such as the so-called mono-glycerides) when heated to high temperatures readily undergo change with elimination of water.

Thus monoacetin loses water at a comparatively low temperature and is converted into polyacetin (diacetyldiglycide). The present author has also observed a similar change with monostearin. If monostearin is heated at 180° C. for several hours, the amount of free hydroxyl in the substance is considerably reduced, as can be shown by determinations of the acetyl value of the product.

There is thus considerable evidence to show that the reactions here formulated may readily proceed under the conditions of polymerisation of fatty oils.

The author recognises, however, that further experimental verification of this theory is needed, especially regarding the formation of a polyglycerol fat during polymerisation, before the theory can be accepted without reserve.

The experiments recorded in this paper were undertaken by Mr. L. V. Cocks, F.I.C., to whom the author's best thanks are due.

NOTES ON THE U.S. GOVERNMENT METHOD OF DETERMINING PHENOLS IN SHEEP DIPS.

BY K. B. EDWARDS, B.S.C., AND G. A. FREAK, B.S.C., F.I.C.

In the U.S. Government method of determining phenols in sheep dips the phenols are isolated from the acidified dip by steam distillation and eventually obtained in benzene solution.* This solution is shaken in a graduated tube with a 1:3 sodium hydroxide solution, and, after the lapse of sufficient time to allow of complete separation, the increase in volume of the alkaline solution is measured. Each cubic centimetre increase in volume is then taken as representing 1 g. of phenols.

Chapin states* that with weighed amounts of pure phenols the coefficient weight of phenols ÷ volume increase of NaOH is constant for a given phenol irrespective of the amount measured or of the presence or absence of other coal tar hydrocarbons in addition to benzene. In support of this the following coefficients, obtained with different weights of "fairly pure cresylic acid," are given:—1.055, 1.078, 1.079, 1.076, 1.070.

In connexion with this coefficient, Chapin says:—"This coefficient is not the same for all phenols, but varies in the same direction as the specific gravity of different phenols, though in greater ratio, accordingly varying inversely as the molecular weights of the different phenols and in approximately equal inverse ratio. For the mixtures of phenols ordinarily occurring in commercial cresylic acid, and in the grades of coal tar creosote oils commonly used for making dips, the average coefficient proved to be unity as nearly as could be determined." He gives, however, no figures obtained with commercial creosote oils or cresylic acids, and, in view of the fact that the commercial products vary to a great extent, it is important to know whether the variation exhibited by the coefficient is large or sufficiently small to be neglected.

TABLE 1.

Phenol.	Coefficient	Weight of phenols Increase in vol. of NaOH*			Apparent % phenols taking coefficient as 1.
		I.	II.	Mean.	
Phenol..	..	1.081	1.075	1.078	92.7
<i>o</i> -Cresol..	..	1.058	1.064	1.061	94.2
<i>m</i> -Cresol..	..	0.995	0.990	0.992	100.7
<i>p</i> -Cresol..	..	0.971	0.950	0.975	102.5

This point has therefore been investigated with results as shown in Table 1. These tests and those

on purified cresylic acid, to be described later, were carried out in the prescribed apparatus, using 10 g. of the pure phenol in 60 c.c. of benzene.

These figures show clearly that the nature of the phenol is all-important, ordinary phenol showing an excess of 8% and *p*-cresol a deficiency of 2.5%. The various xylenols were not available for test at this time, but results of tests made by one of us some nine years ago with pure xylenols indicated that the increase in the molecular weight would result in still further discrepancy. This is confirmed by the results obtained with different fractions of purified cresylic acid. Commercial cresylic acid was purified by dissolving it in an excess of sodium hydroxide solution, distilling with steam in order to remove neutral oils and bases, and recovering the phenols by treatment with acid. These phenols were then divided into fractions by distillation from a flask fitted with a four-bulb Young fractionating column. In addition, a portion of the acid was completely distilled until decomposition commenced in the flask, the product being designated below as "complete mixed distillate."

Table 2 shows the results obtained:—

TABLE 2.

Fraction.	Apparent % of Coefficient. phenols (coefficient 1).	
Below 195° C. ..	1.052	95.0
195°-197° ..	1.042	96.0
197°-200° ..	1.026	97.5
200°-205° ..	1.015	98.5
205°-215° ..	0.990	101.0
215°-225° ..	0.943	105.5
225°-235° ..	0.922	108.5
235°-250° ..	0.900	111.5
Above 250° (to about 300°) ..	0.851	117.6
Complete mixed distillate ..	0.985	101.6

Comparison of Table 2 with Table 1 shows that the cresylic acid fractions behave in a manner analogous to the isolated phenols, i.e., the coefficient is less for the higher-boiling compounds.

It is therefore obvious that the method is open to serious objection, inasmuch as a low-boiling acid, which will contain a large proportion of phenol and *o*-cresol, may yield results considerably below the truth.

It may be contended that an error of about 5% is not a serious one in a method designed to estimate cresylic acid in sheep dips containing, say, 20% of phenols. Unfortunately, however, this United States Government method has been recommended as the standard test in evaluating cresylic creosotes, and cresylic acids bought for sheep dip and disinfectant purposes, and American buyers appear invariably to test material by this process. Cresylic acid for the American market is almost invariably supplied to a specification as to percentage and boiling points, and in our experience the specifications usually indicate a demand for cresylic acid having a large percentage of *o*-cresol. It will be seen from the above figures that when such an acid is supplied the method of testing must show the purity as being 4-6% below the true content of phenols; such a difference on a very large shipment represents a considerable sum of money. The authors have in mind a specification which demanded that 60-70% of the cresylic acid supplied should boil between 185° and 195° C. This specification invariably was the cause of claims for impurity to a very large sum, inasmuch as acids containing 97% of cresols showed 92%, according to this test. It should also be noted that the test is only designed for dealing with phenols boiling between 185° and 250°, inasmuch as the phenols have to be steam distilled, and phenols boiling above 250° are extremely difficult to volatilise with steam. The British test upon which creosote oils are evaluated does not make any such distinction, and phenols are usually estimated by removal from the oil with caustic soda solution of sp. gr. 1.10. There are many

* The analysis of coal-tar creosote and cresylic acid sheep dips.
R. M. Chapin. Bulletin 107, Bureau of Animal Industry, U.S. Dept. of Agri., 1908.

creosotes produced to-day in which a considerable proportion of the phenol content boils above 250° C., and such creosotes are likely to increase in number, owing to the various forms of low-temperature carbonisation employed. Such creosote oils will show extremely erratic results when tested by the American method as compared with the usual method adopted in this country, and the American specification will shut out any creosote containing a large proportion of these valuable disinfectant substances.

It will be clear from the figures given in this paper that phenols boiling above 250° C. show a considerably higher degree of purity than is actually present. Against this, however, must be placed the fact that such phenols will not volatilise with steam within the limits for practical estimation. There are, therefore, two balancing factors which will tend to produce results which in isolated cases may be somewhere near the truth but are by no means to be relied upon.

There is at present a very great need for a simple and accurate test for the determination of the purity of cresylic acids. The standard method of the text-books, namely, extraction by ether or petroleum spirit from an alkaline solution, is by no means reliable in the presence of very high-boiling phenols or in the presence of relatively large percentages of bases which are apt to volatilise in the removal of the solvent. In our experience the percentage figures attached to cresylic acid obtainable in the open market are purely nominal, there being extremely few makes of cresylic acid which can be relied upon to be of 98% purity, although practically all pale cresylic acid is sold as 97–99%. A 97% acid is difficult to obtain in actual practice except at a greatly enhanced price, and very many of the so-called 97–99% cresylic acids contain not more than 94% of pure phenols. A recent sample of white “99% cresylic acid” examined by the authors contained less than 97% of the pure phenols.

THE DISTRIBUTION OF ENZYMES AND PROTEINS IN THE ENDOSPERM OF THE WHEAT BERRY.

BY F. J. MARTIN, M.A.

In the separation of flour by the process of gradual reduction, now in general use in the milling industry, different parts of the wheat berry tend to segregate at various points of the mill; it is therefore of great interest and importance to the miller to know how far and in what manner the proteins and enzymes that occur in the wheat berry are liable to vary.

Jago (“Technology of Bread-making,” p. 371) describes a method by which the uneven distribution of the protein in the wheat berry may be demonstrated qualitatively. The starch is removed from a cross-section of the grain, which is then stained with Millon’s reagent; the gradual concentration of the gluten in the endosperm as the cortex is approached is evidenced by the vivid coloration of the protein fibrils. Richardson (*ibid.*, p. 351), who made a very complete examination of the mill products from various mills, shows in his analyses that there is a very wide variation in the gluten content of flours produced at various parts of the mill. As experience does not show that the flour from the tail of the mill is of much greater “strength” than flour from the other reductions, an examination of the milling products, representing flour from different parts of the endosperm, was carried out.

The work recorded in this paper was carried out to investigate the nature and extent of the variations, if any, in the flour from different parts of

the wheat berry with respect to enzymic activity and quantity and quality of gluten.

In order to avoid any segregation effects due to the milling of a mixture of wheats, a single wheat, Barusso Plate, was milled for this experiment. Samples of flour were taken as follows:—

(a) Reduction flours:—

(1) From ABC reductions, corresponding to the central portion of the grain.

(2) From DEG reductions corresponding to a region exterior to the central portion.

(3) From K reductions corresponding to a layer nearer the cortex than DEG.

(4) From MN reductions corresponding to the region nearest the cortex.

(b) Break flours:—

(1) From BM₁, a flour from the central portions of the grain.

(2) From Br₁, a flour having its origin near the cortex.

(c) Straight grade flour—representing the entire endosperm.

Enzymic activity and quantity of gluten.—The germ is always regarded as the seat of enzymic activity, but since in the process of modern milling the germ is practically all eliminated and collected separately, an examination of the various flours was made to see how far the endosperm was homogeneous as regards diastatic strength. The enzymic activity was measured as suggested by Wood (J. Agric. Sci., 1907, 2, 139) by the amount of gas the flour was capable of producing in 24 hours when fermented with yeast. A dough was made up of 10 g. of flour and 5 g. of water, with 1·2% of salt and 1·0% of yeast; the temperature was maintained at 29° C. and the carbon dioxide collected for 24 hours. The results are given in Table I.

The gluten in all the samples was estimated by first washing away the starch and then weighing both while wet and after drying at 100° C.

TABLE I.

Flour.	Amount of CO ₂ in c.c.	Wet gluten. %	Dry gluten. %
a 1 ..	85	40·0	13·8
a 2 ..	93	46·5	15·9
a 3 ..	115	50·2	17·4
a 4 ..	122	53·6	17·9
b 1 ..	58	45·4	15·9
b 2 ..	83	63·5	21·6
c ..	88	45·3	15·6

It will be seen that the enzymic activity of the flour increased from the centre to the exterior of the endosperm, the variation being represented by 58 c.c. and 122 c.c. in the extreme cases.

The quantity of gluten is least in the centre of the grain and increases towards the exterior of the endosperm. In the case examined the extremes stated as dry gluten were 13·8% and 21·6% respectively.

Quality of gluten.—The rather large difference in the amounts of gluten present in the various flours examined suggested that these differences would be reflected in the baking tests; but previous experience had not borne this out. It was therefore thought that the quality of the gluten from the various parts of the grain might vary. In handling the glutens separated by washing it was noticed that the gluten removed from the flour obtained from the centre of the grain was of a more elastic and rubber-like consistency than that from the flour from near the cortex, the differences in characteristics between the extremes being very marked.

In order to test the gas-retaining capacity of the gluten from various parts of the wheat berry the

flours from the different points of the mill were mixed with a calculated amount of wheat starch so that each mixture of flour and wheat starch contained the same amount of gluten. Doughs were made up of flour and wheat starch 20 g., water 11 g., salt 1.2%, yeast 1.0%, and fermented at 29° C. in graduated cylinders, the carbon dioxide generated being collected over brine. The volumes of the doughs and the gas generated were read at frequent intervals. Curves constructed from these figures gave the gas-retaining power of the gluten (Martin J., 1920, 146 r). The gluten of the flour from the ABC reductions (a1) showed the greatest capacity for gas-retaining, and for the purpose of this paper the gas-retaining power of this gluten is taken as 1.00 and the other glutes referred to this standard; the results are given in Table 2.

Gas-retaining capacity of the flours.—The gas-retaining capacity of the flour was calculated by multiplying the percentage of gluten in the flour by the gas-retaining capacity of the gluten; the results are also given in Table 2.

TABLE 2.

Flour.	Relative gas-retaining capacity of gluten.	Dry gluten. %	Gas-retaining capacity of flour.
a 1	1.00	13.8	13.8
a 2	0.93	15.9	14.8
a 3	0.86	17.4	14.9
a 4	0.77	17.9	13.8
b 1	0.86	15.9	13.7
b 2	0.64	21.6	13.8
c	0.90	15.6	14.0

There is thus a considerable difference in the gas-retaining capacity of the gluten from different parts of the wheat berry, the better qualities of gluten being found in flour from the central portions of the endosperm, but the variations in the quantity of the gluten, which increases from the interior to the exterior of the endosperm, are practically counterbalanced by the variations in the quality of the gluten, which progressively deteriorates from the centre to the outer parts of the endosperm, and flour of a more or less uniform "strength" is produced. The flours from DEG and K reductions (a2 and a3), however, appear to be slightly stronger than the others.

Confirmatory trials.—The results of the above tests were confirmed by baking trials. It was not thought advisable to bake the Barusso Plate flours by themselves on account of their low gas-producing capacity and high gluten content. Each sample of flour was therefore mixed with an equal weight of flour from English wheat, of high diastatic capacity and low gluten content. The English flour had a

gas-retaining capacity of 8.0 when referred to the standard used for the Barusso Plate, so that the gas-retaining powers of the mixtures, by calculation, were as shown in Table 3. The gas-producing capacity of the English flour was 253 c.c. when estimated under the same conditions as the Barusso Plate flour. The calculated diastatic capacities of the mixed flours are also given in Table 3. The addition of a percentage of another flour had the effect of reducing proportionally any differences originally present in the Barusso flours, but this could not be avoided.

The loaves were baked on the short straight dough process, the fermentation in the troughs lasting four hours. Sufficient flour was included in each trial to make ten "cottage" and two "tin" loaves. Bakers marks were awarded by Mr. A. E. Humphries, under whose supervision these trials were made (Table 3). It will be seen that the different batches were so alike with respect to "strength" that they were awarded the same mark.

TABLE 3.

Flour 50% English and 50% as below.	Calculated gas-producing power of mixed flour in c.c.	Calculated gas-retaining power of mixed flour.	Baker's mark.
a 1	169	10.9	82
a 2	173	11.4	82
a 3	184	11.5	82
a 4	188	10.9	82
b 1	156	10.9	82
b 2	168	10.9	82
c	171	11.0	82

Summary.—(1) The distribution of the enzymes and proteins in the wheat berry has been investigated. It has been found that the enzymic activity, as shown by the evolution of carbon dioxide on fermentation, increases progressively from the interior to the exterior of the endosperm.

(2) The quantity of gluten increases in the same manner.

(3) The quality of the gluten varies considerably, being good in flour from the interior of the endosperm and deteriorating progressively in flour from regions approaching the cortex.

(4) The effect of the combination of the increasing quantity with decreasing quality of gluten tends to produce flours of a common "strength" from various parts of the wheat berry.

In conclusion, the author wishes to express his thanks to Mr. A. E. Humphries for permission to make use of figures obtained while working at Coxes Leck Milling Co., Weybridge.

MR. W. MCD. MACKEY IN THE CHAIR.

A GRAPHICAL METHOD FOR THE INTERPRETATION OF FLUE GAS ANALYSES.

BY GILBERT B. HOWARTH.

[Department of Coal Gas and Fuel Industries, the University, Leeds.]

Complete tests of the thermal efficiency of boilers, furnaces, and similar appliances generally involve a series of laborious calculations intended to determine:—

(1) The ratio of the amount of air supplied for combustion to the minimum amount of air theoretically required for complete combustion, and

(2) The ratio of the amount of heat in the hot flue gases to the amount of heat liberated by the combustion of the fuel.

If these calculations can be generalised in such a way that the results may be represented on a system of co-ordinates, the determinations may be effected rapidly from the smallest possible number of experimental data.

The combustion with excess of air of any fuel containing only carbon, hydrogen, oxygen, and nitrogen may usually be regarded as producing flue gases composed of a mixture of carbon dioxide, water vapour, oxygen, and nitrogen. In the usual processes of gas analysis water is eliminated and the composition of the dry gas obtained. The ratio of the volume of water vapour in the flue gases to the volume of carbon dioxide is equal to half the ratio of hydrogen atoms to carbon atoms in the fuel.

The composition of the dry flue gases may be completely defined by a statement of the percentages of any two of the dry constituents (say oxygen and carbon dioxide), the percentage of the third (in this case nitrogen) being obtained, if required, by difference. These quantities may be calculated for the combustion of any given fuel with any given percentage excess of air by constructing a chemical equation. Thus there are four variable quantities:—

P=Percentage of oxygen in the dry flue gases.

Q=Percentage of carbon dioxide in the dry flue gases.

x =Extra air, expressed as a percentage of the minimum quantity of air theoretically required for complete combustion.

n =A quantity depending on and to be calculated from the composition of a fuel, and which is the same for those fuels (and no others) which, when burnt with a given percentage of extra air, give flue gases of the same dry composition,

and from any given values of n and x it is possible to construct a chemical equation, and from it to calculate corresponding values of P and Q.

Suppose that the values of P and Q calculated for a number of values of n and x are plotted on a system of rectangular co-ordinates, and that lines are drawn through all points obtained from the same value of n , and another series of lines through all points obtained from the same values of x . The

two series of lines thus drawn will constitute an irregular grid superimposed on the original rectangular grid. This double grid constitutes the basis of the "graphical method" to be described in this paper. It will be seen that for any point on the diagram the four quantities, P, Q, n , and x may be read off at once on the two grids. Moreover, any two of the four quantities are sufficient to define a point on the diagram from which the other two quantities may be obtained at once by inspection.

The commonest use of the diagram for industrial purposes is the following:—The "fuel factor" (n) being known from the composition of the fuel, the only observation required is the percentage of carbon dioxide in the dry flue gases in order to obtain accurately from the diagram the percentage of oxygen in the dry flue gases and the percentage of extra air. Moreover, if the composition of the fuel is not known, the value of n can be found from the diagram by a single determination of carbon dioxide and oxygen in the dry flue gases.

The calculation of the co-ordinates of multitudes of points from a corresponding number of chemical equations (as supposed in the preceding paragraph) is not actually required in practice. The chemical equation representing the combustion of C_aH_b with $x\%$ of extra air containing $A\%$ of oxygen is the following:—

From this it is seen that

$$a + 0.01x(a+b/4) + (1+0.01x)(a+b/4)(100/A-1)$$

volumes of dry flue gases contain a volumes of CO_2 and $0.01x(a+b/4)$ volumes of O_2

Then percentage of oxygen = $P =$

$$\frac{x(1+b/4a)}{1+0.01x(1+b/4a) + (1+0.01x)(1+b/4a)(100/A-1)}$$

and percentage of carbon dioxide = $Q =$

$$\frac{100}{1+0.01x(1+b/4a) + (1+0.01x)(1+b/4a)(100/A-1)}$$

Since the values of P and Q for a given value of x depend only on the ratio b/a , we may accept this ratio as fulfilling the function of the quantity n mentioned above. Hence we may put $n=b/a$. Then if $A=21.0$, from these two expressions, by the elimination of x , the following general equation for the "fuel lines" is obtained:—

$$P + (1+0.1975n)Q = 21.0$$

which is the general equation of a series of straight lines (one for every value of n), all of which pass through the point (21,0).

By the elimination of n from the same expressions, the following general equation for the "extra air lines" is obtained:—

$$(376/x + 4.76)P + Q = 100$$

which is the general equation of a series of straight lines (one for every value of x), all of which pass through the point (0,100).

These results, shown graphically in the extra air diagram (fig. 1), are quite in accord with the disposition of the lines that might be expected from general considerations.

It should be noted that when $P=0$ (i.e., complete combustion without excess of air) the equation of the fuel lines becomes

$$Q = 21.0 / (1 + 0.1975n)$$

thus giving the percentage of carbon dioxide obtainable in such ideal conditions.

It has been shown above that any hydrocarbon may be completely defined for the present purpose by the ratio of the number of atoms of hydrogen to the number of atoms of carbon accompanying them, i.e., $n = H/C$. Thus, for example, n is 1 for benzene or acetylene, 2 for olefines, 2.4 for pentane.

The Extra Air Diagram.

FIG. 1.

Other methods of defining hydrocarbons (e.g., by the gravimetric percentage of one of the elements, etc.) may be used, provided that the numbers attached to the fuel lines on the "Extra air diagram" are amended accordingly.

It is evident that the addition to or removal from a fuel of oxygen and hydrogen in the proportion to form water will have no influence whatever on the composition of the dry flue gases. Thus, to obtain n we must subtract from the number of atoms of hydrogen two atoms of hydrogen for every atom of oxygen in the fuel and divide the remaining number by the number of atoms of carbon, i.e., $n = (H - 2O)/C$. Where a fuel is rich in oxygen, the value of n thus obtained may be negative; thus for carbon monoxide $n = -2$, and for carbon dioxide $n = -4$.

The majority of pure combustibles may be dealt with by the formula $n = (H - 2O)/C$. For example, n is 2 for alcohol or ether, and 0 for carbohydrates.

Nitrogen in the fuel is assumed to be associated with a portion of the oxygen in the proportion to

form air. Thus, for example, the products obtainable by the complete combustion of $C_aH_bO_cN_d$ without excess of air will have the same composition as those obtainable by the complete combustion of $C_aH_bO_{c-d/3.76}$ without excess of air. This suggests that the value of n is the same for both substances and is equal to $\{b - 2(c - d/3.76)\}/a$ or, using chemical symbols, $n = (H - 2O + 0.532N)/C$. But the minimum quantity of air required for the combustion of a molecule of $C_aH_bO_cN_d$ is $a + b/4 - c/2$ volumes and for the combustion of a molecule of $C_aH_bO_{c-d/3.76}$ is $a + b/4 - (c - d/3.76)/2$ volumes, and any extra air supplied is measured as a percentage of one or other of these two quantities according to the formula used to represent the combustible. Therefore the percentage of extra air given by the chart (which utilises the second expression) must be converted into the units obtainable by actual measurement (according to the first expression) by multiplying by

$$(a + b/4 - c/2 + d/7.52)/(a + b/4 + c/2).$$

In other words, the chart readings (x) must be increased by a certain fraction, $\delta x/x$, viz.,

$$\frac{\delta x}{x} = \frac{d/7.52}{a + b/4 - c/2} = \frac{0.532d}{4a + b - 2c}$$

or, reverting to the use of chemical symbols, the correction to be added to the percentage of extra air given by the chart

$$= \delta x = \frac{0.532N}{4C + H - 2O} \cdot x$$

In the same way, if the percentage of extra air is included in the data, this ($x + \delta x$) must first be reduced to the chart readings (x) by subtracting the following correction from the percentage of extra air as given:—

$$\delta x = \frac{0.532N}{4C + H - 2O + 0.532N} \cdot (x + \delta x)$$

For many industrial purposes (for example, routine tests to regulate the supply of secondary air to a gas-fired furnace) absolute values of the extra air are not essential, and relative values are almost as useful in controlling the approach to the theoretical minimum. In this case the correction δx need not be applied, the figures obtained being regarded as relatively correct. The errors thus introduced become smaller as the theoretical minimum of air is approached. Or an approximation may be made by using a simple empirical formula applicable to a given class of fuel.

An alternative method of dealing with nitrogen is based on the fact that the addition of nitrogen to a fuel reduces the proportions of oxygen and carbon dioxide in the flue gases in the same proportion. Though this treatment is not usually convenient in practice, it provides an interesting confirmation of the arguments used above and a simple method of verifying the accuracy with which the diagram is drawn.

We may consider that the combustible sulphur in the fuel burns completely to sulphur dioxide. Atoms of sulphur should be added to atoms of carbon, the SO_2 being recorded as CO_2 in the flue gas analysis. The molecular ratio of the two gases will evidently be the same as the atomic ratio of the elements. In practice the proportion of sulphur in the fuel is usually small, and the presence of this element may be ignored, or its quantity assumed to have a suitable average value for all fuels of a given type.

The above formulæ deal with the atomic composition of the fuel. It will be clear that they may be adapted to suit gravimetric composition, or, in the case of gases, volumetric composition. These formulæ are summarised in Table I.

The part of the "Extra air diagram" above and to the right of the line corresponding to $n = -4$ and $x = \infty$, and the part below the P-axis ($n = \infty$) do not appear to be applicable to ordinary industrial fuels.

The region to the left of the Q-axis involves negative values for the extra air and oxygen. Evidently this area covers the important case of *incomplete combustion*, where the negative percentage of extra air implies a deficiency of air and the negative percentage of oxygen implies the presence of an equivalent quantity of unconsumed combustibles. It seems possible that this region might be utilised by considering separately the fuel factor of the fuel burnt, and the fuel factor of the combustible material remaining in the flue gases. But the process becomes very complex when combustion is seriously incomplete.

For any physical properties of the dry flue gases that may be calculated from their composition (e.g., density, heat capacity over any stated range of temperature, etc.) further series of lines may be drawn on the "Extra air diagram." The determination of carbon dioxide in the dry flue gases may then be replaced by a determination of any physical property for which curves have been prepared. In practice it may be more convenient to make the measurements on the flue gases saturated with water vapour at a pre-arranged temperature, this modification being taken into account in the calculation of the curves to be superimposed on the extra air diagram.

The author has no difficulty in using an extra air diagram photographically reduced from the original large and complex diagram to a size of about 2 in. \times 3½ in. For industrial purposes it is suggested that a diagram about 30 in. \times 18 in. with many more lines should be reproduced by lithography in a single colour (to avoid registration troubles). From such a diagram, suitably mounted on sheet zinc, or three-ply board, any draughtsman could trace the lines in distinct colours, the tracing being confined to that part of the diagram that was of particular interest for the purpose in view.

The composition of the dry flue gases being known, either by actual analysis or by the use of the diagram already described, the thermal capacity of the dry flue gases over any given range of temperature may be calculated from the mean specific heats at constant pressure of the various constituents over the given range.

From the large number of specific heat determinations that have been made the calorimetric measurements up to 1400° C. carried out by Holborn and Henning may be selected. Their results are so arranged as to give for each gas the mean specific heat at constant pressure from 0° C. to t° C. in the form of a linear or quadratic expression in t . (For water vapour 100° C. forms the lower limit.) Since oxygen and nitrogen have practically the same molecular specific heats, Q and t are the only data required for the calculation of the heat contained in a given amount of the dry flue gases. Moreover, since the weight of carbon burnt in the formation of this quantity of dry flue gas can easily be found, the quantity of heat in the dry flue gases formed during the combustion of unit weight of carbon may be obtained. The equation connecting this quantity with Q and t is the general equation of the curves forming the upper part of the "Thermal diagram" (fig. 2). It will also be recognised that, of this quantity of heat per gram of carbon, the quantity of heat per gram of carbon contained in the carbon dioxide alone is given by the curve corresponding to $Q=100$.

The lower part of the thermal diagram shows the total heat (sensible plus latent) contained in the water vapour accompanying the above quantity of dry flue gases. For any given temperature this may be expressed in terms of K , which is the ratio of hydrogen atoms to carbon atoms in the fuel burnt. Evidently the total heat in the whole flue gases per gram of carbon burnt is the sum of these two quantities (i.e., for dry flue gases and for water vapour), and is obtained by measuring along the ordinate corresponding to the observed temperature the intercept between the curve corresponding to Q (the percentage of carbon dioxide in the dry flue gases) and that corresponding to K (the ratio of hydrogen atoms to carbon atoms in the fuel burnt).

The Thermal Diagram.

FIG. 2.

According to Holborn and Henning the mean specific heats at constant pressure from 0° C. to t° C. (in calories per gram) are as follows:—

$$\begin{aligned} \text{N}_2 & 0.2350 + 0.000019t \\ \text{CO}_2 & 0.2010 + 0.0000742t - 0.000000018t^2 \\ \text{H}_2\text{O (from 100° C.)} & 0.4669 - 0.0000168t + 0.000000044t^2 \end{aligned}$$

Calculation from these gives:—

$$\begin{aligned} \text{Heat in dry flue gases per gram of carbon burnt} \\ = (54.83t + 0.00443t^2)/Q + 0.189t + 0.000228t^2 \\ - 0.000000066t^3 \end{aligned}$$

from which the upper part of the thermal diagram may be plotted. Also total heat in water vapour produced during the combustion of 1 g. of carbon

$$= K(445.0 + 0.3515t - 0.0000159t^2 + 0.000000033t^3)$$

from which the lower part of the thermal diagram may be plotted.

The expression "Theoretical flame temperature" is often used to denote that temperature at which, when a fuel is burnt with the minimum quantity of air, the heat in the flue gases is equal to the heat developed by the combustion of the fuel. Occasionally a specified fraction of the heat developed by combustion is employed, in order to

allow for radiation losses from the flame. Evidently this temperature may be found by means of a thermal diagram resembling that already described. However, in general the "theoretical flame temperature" of industrial fuels lies between 1500° C. and 2500° C.—beyond the scope of Holborn and Henning's specific heat determinations. The most convenient data to use are those collated by Lewis and Randall (J. Amer. Chem. Soc., Sept., 1912), who modified a large variety of experimental results to agree with theoretical requirements, thus obtaining simple formulæ likely to be reasonably accurate over a wide range of temperature, certainly up to 2000° C.

As in this case the fuel is always supposed to be burnt with the theoretical minimum quantity of air, we may substitute for Q the value given previously—when $P=0$, $Q=21.0/(1+0.1975n)$, so that the lines in the upper part of the diagram may be labelled with values of n instead of with values of Q . Then, n and K being known from the analysis of the fuel, and the calorific value of the fuel per gram of carbon being obtained, the "theoretical flame temperature" may be read from the diagram (fig. 3).

The Flame Temperature Diagram.
FIG. 3.

As before, the heat contained in the carbon dioxide alone is given by the curve corresponding to $n = -4$.

According to Lewis and Randall the specific heats at constant pressure at T° C. absolute (in calories per g.-mol.) are as follows:—

$$\begin{aligned} \text{N}_2 \text{ and O}_2 & 6.5 + 0.0010T \\ \text{CO}_2 & 7.0 + 0.0071T - 0.00000186T^2 \\ \text{H}_2\text{O} & 8.81 - 0.0019T + 0.00000222T^2 \end{aligned}$$

Calculation from these gives:—

Heat in dry flue gases per gram of carbon burnt

$$= n(0.531t + 0.0000392t^2) + 2.854t + 0.000411t^2 - 0.00000052t^3$$

from which the upper part of the flame temperature diagram may be plotted.

Also total heat in water vapour produced during the combustion of 1 g. of carbon

$$= K(445.0 + 0.3523t - 0.00001458t^2 + 0.0000000308t^3)$$

from which the lower part of the flame temperature diagram may be plotted.

TABLE I.

SUMMARISED FORMULÆ.

From atomic composition.

$$n = (H - 2O + 0.532N) / (C + S)$$

$$\delta x / x = 53.2N / \{4(C + S) + H - 2O\} \%$$

$$K = H / C$$

From gravimetric composition.

$$n = (4H - \frac{1}{2}O + 0.152N) / (\frac{1}{3}C + \frac{1}{8}S)$$

$$\delta x / x = 15.2N / \{4(\frac{1}{3}C + \frac{1}{8}S) + 4H - \frac{1}{2}O\} \%$$

$$K = 12H / C$$

From volumetric composition of gases.*

$$n = [6C_3H_8 + 4\{CH_4 - (CO_2 + O_2)\} + 2(H_2S + H_2 - CO) + 1.064N_2] / (3C_3H_8 + CH_4 + CO + CO_2 + H_2S)$$

$$\delta x / x = 53.2N_2 / (9C_3H_8 + 4CH_4 + 3H_2S + CO + H_2 - 2O_2) \%$$

$$K = (6C_3H_8 + 4CH_4 + 2H_2 + 2H_2S) / (3C_3H_8 + CH_4 + CO + CO_2)$$

Approximations (subject to amendment).

For coals (gravimetric composition).

$$\delta x / x = \frac{1}{3}N\% \text{ but is practically always negligible.}$$

For industrial gases over 400 B.Th.U. (gross) per cub. ft.

$$\delta x / x = (300 \times N_2) / (2 \times \text{cal. val.}) \%$$

(from volumetric composition).

For industrial gases under 400 B.Th.U. (gross) per cub. ft.

$$\delta x / x = (700 \times N_2) / (4 \times \text{cal. val.}) \%$$

(from volumetric composition).

DISCUSSION.

Mr. HUDSON pointed out that the quality of fuel was very variable even throughout the same commitment, and expressed a doubt as to the applicability of the method to ordinary works conditions.

The CHAIRMAN asked if the method could be adapted to the ordinary fuel analysis results expressed as volatile matter etc.

Mr. TUTTON said that it was most important in works practice not to rely entirely on the percentage of carbon dioxide in the flue gas. Unless carbon monoxide was estimated the deductions made only from the dioxide figure might be very misleading.

Prof. COAN said that the present scheme was a great advance on the work of Bunte, who had had to construct a separate table for each fuel. The author's graphs were applicable to practically all fuels and resulted in an enormous saving of time and trouble when it was necessary to calculate flue gas analyses in terms of heat loss, excess of air, and flame temperature.

The AUTHOR, in reply, pointed out that the values of n for all the coals given in Table II., ranging from lignite to anthracite, lay between 0.63 and 0.40, representing a difference of only about 0.5 in the CO₂ percentage, and that the much smaller accidental variations in quality could usually be ignored. The conversion of fuel analyses from terms of volatile matter etc. into ultimate analyses was quite a different problem and was not touched on in the present paper.

portion dealing with research carried out at the Research Department, Woolwich, has been published in the Journal of the Chemical Society and in this Journal by Drs. Gibson and Masson, Messrs. McCall, Spencer and Barrett, and Miss Jacobs; the second portion forms the subject of this paper.

In the chemical industries employing cellulose as their fundamental raw material the systematic scientific attention given to the physical properties of the cellulose and the relation of these to the physical properties of its derivatives required for producing the ultimate finished product was, until recently, small in relation to its importance. It was of course known that certain types of cellulose gave better results from the physical point of view than others, and a selection as the result of experience was thus made. The desired results were not then obtained through scientific knowledge of the properties of the cellulose used, but by the methods of manufacture of its derivatives. These methods also were adopted as the result of long and expensive experience rather than by a scientific knowledge admitting explanation of the way in which the various factors in the processes affected the properties of the derivatives. The ultimate products of the cellulose chemical industries comprise mostly the results of the further treatments of the cellulose derivatives prepared. From the choice of the raw material to the application of the finished product the colloidal nature of the cellulose is generally a controlling factor.

From this point of view the stages of manufacture are all inter-connected, and generally it is advisable to control them all as far as possible, commencing at the bottom with the selection of the raw cellulose material and the treatment to be given to it in its purification. It is in this particular section that published information is most lacking and practice actually most backward. The essential physical property of cellulose and its derivatives from the practical point of view is viscosity, and in the processes for the manufacture of artificial silks, celluloid and plastics, cellulose varnishes, lacquers, etc., viscosity determinations of the cellulose derivatives have already become important, though the methods followed and the results obtained have not been traced back to show definite relationships throughout.

During the war the nitrocellulose industry in its particular application to propellant explosives manufacture became pre-eminent, and the results which had been obtained in this work to the date of the Armistice have been concerned with this particular section of the industry, which was under

Communications.

COTTON CELLULOSE.

THE APPLICATION TO INDUSTRY OF RECENT RESEARCHES ON ITS VISCOSITY.

BY R. A. PUNTER, B.SC., A.I.C.

Introduction.

In carrying out the work now under report, the closest co-operation between business, technology and research was maintained. For publication it has been thought desirable to divide the report into two sections, namely, research, and the application of the results of this research. The

the directorship of Sir F. L. Nathan, K.B.E., Department of Explosives Supply, Ministry of Munitions of War.

For the manufacture of nitrocotton for propellants before the war, cotton waste chiefly from the home spinning mills was used after purification. The purification was carried out by a number of small firms who supplied their products direct to propellants manufacturers, and the product supplied was required to conform to a Government specification dated March 23, 1908. This specification gave considerable latitude to the mills both in the choice of the raw materials and in the purification treatment which could be followed. It aimed at the preclusion, to what was considered a sufficient extent, of materials other than normal resistant cellulose without any reference to the effect which the treatments employed for attaining this object might have on the colloidal properties of the cellulose and on subsequent manufacture.

The importance of this side of the question had been realised by the Research Department, Royal Arsenal, Woolwich, before the war, but as the research was comprehensive it had to give place to other more urgent problems after a preliminary report dealing with viscosity was issued in 1914. Until towards the end of 1915 nothing further was done, and in the interval the production of cotton waste for propellants, largely in the hands of a company (the British and Foreign Supply Association, owning eleven out of eighteen cotton waste purification mills and producing 80–90% of the total production in agreement with the Ministry of Munitions) had been increased to about 1000 tons per week. To meet this production about 1500 tons of raw materials had to be treated per week, necessitating the heavy importation of a large variety of cotton cellulose materials. Very crude methods of treatment were in general followed without any technical supervision. The purified wastes, although complying with the specification, were very different in physical properties, which affected subsequent manufactures, and the price of the waste had risen in the beginning of 1916 to £75 per ton from the pre-war figure of £44 per ton.

In 1916 a shortage of bleaching powder, difficulties connected with the colloidal properties of the materials, experienced in the manufacture of the new cordite R.D.B., and the decision to undertake the manufacture of the American nitrocellulose powder in this country caused the research investigations to be renewed.

In May, 1917, satisfactory methods for the determination of the viscosity of cellulose prepared from cotton wastes and of nitrocellulose had been established by the Research Department, Woolwich (*cf.* Gibson, Spencer, and McCall, *Chem. Soc. Trans.*, 1920, 117, 479; Gibson and Jacobs, *ibid.*, 473), and from these it was found that:

(1) Considerable variations in the viscosities of the purified cottons from the different mills existed.

(2) The causes of the variations in these viscosities were due to some extent to the purification treatments followed, the main factors being the conditions of the soda boiling treatment.

(3) The viscosity of cotton cellulose bore a direct qualitative relation to the viscosity of the nitrocellulose prepared from it in the laboratory.

It was already known that the viscosity of the nitrocotton influenced the amount of solvent required in the actual manufacture of propellants, but little attention had been paid to this point in practice.

The stage had therefore been reached at which useful experimental work on a large scale could be undertaken, and Sir Frederick Nathan, with Mr. P. Tainsh and the author, arranged, in collaboration with the Research Department, Woolwich, for a comprehensive series of experiments with the

object of providing a more uniform, cheaper, and more suitable cotton cellulose for the manufacture of cordite R.D.B.

At the same time a provisional treatment pending the result of these experiments and based on the results already available was agreed upon, and issued to the mills. The following is the treatment which was issued:

1. *Blending*.—The blending of the raw materials is to be done carefully in the proportions in which they are received. Where possible, blending of the raw materials is to be carried out before kiering.

2. *Kiering*.—Each kier is to be charged with a fixed quantity of cotton and kiered with a definite proportion of alkali solution of constant strength. The solution is to be prepared outside the kier and the sediment allowed to settle; it should give 3.0% free caustic soda and should contain sufficient sodium carbonate to render the liquor at the end of the boil alkaline to the extent of approximately 1% as NaOH.

The time and pressure of the boiling is to be always the same for each kier and as far as possible is to be 10 hours at 40 lb. At certain mills where kiers boiling at two or three different pressures are in operation, the products from these kiers are to be blended in the ratio of the output of the kiers. After kiering the alkaline liquor is to be displaced from the cotton before the latter is removed from the kier.

3. *Black washing*.—As at present.

4. *Bleaching*.—The cold bleaching liquor, prepared apart from the cotton and settled, is to be of definite strength, approx. 0.1% available free chlorine. Circulation during bleaching to be as effective as possible. Bleaching to be continued for a definite period, and the liquor to be run off and the cotton washed before souring.

5. *Souring*.—The acid solution is to be of sufficient strength to reduce the ash of the cotton to specification (about 0.5% as H_2SO_4 , or lower if possible).

6. *Washing, etc.*—Cotton to be washed till neutral, hydro-extracted, wet-willowed where possible, dried at 95–100° C., dry-willowed, and teased.

None of the results obtained from the work done by the Research Department, Woolwich, up to this stage have been given, as these are being included in the publications referred to above.

Work on the preparation of a cotton suitable for nitrocellulose powder followed on similar lines to the work done for cordite R.D.B., but at a later date, and was guided by the latter. It is dealt with in a subsequent section of this paper.

Experimental work on the preparation of cotton cellulose for cordite R.D.B.

Throughout the mills various types of plant were in operation, particularly in regard to kiers, comprising open vessels up to vessels passed for and worked at 80 lb. steam pressure, though of material boiled at pressures higher than 40 lb., the output could be but small. It appeared from previous work that 40 lb. pressure would be sufficient to give, from the raw materials to be used, a purified cotton with a viscosity as low as it was thought would be required.

Plant capacity determined the maximum initial ratio of solution to cotton in the kiers at 4 to 1.

The following experiments were arranged to determine a method of preparation of cotton waste most suitable for the manufacture of nitrocotton for cordite R.D.B.:—

Series 1.

It is known that the character of the cotton waste used is related to the resistance offered by the

cordite R.D.B. dough in the presses and in consequence to the quantity of solvent required for incorporation, and it is thought that this again is related to the viscosity of the nitrocellulose and possibly also to that of the raw cotton. It was decided to ascertain empirically the effect on the character of the cordite dough of the various factors under control in the preparation of the waste, and, if possible, to obtain a test which when applied to the waste would afford an indication of its suitability for cordite manufacture in this respect.

The raw materials available were:—

- (A) English spinners' sweeps, degreased.
- (B) American spinners' sweeps, non-degreased.
- (C) Eastern spinners' sweeps, non-degreased.
- (D) American willowed fly.
- (E) Eastern card fly.
- (F) American cops.
- (G) Eastern cops.

The English spinners' sweeps contained 17·3% of oil and was, therefore, initially degreased by extracting three times with benzene, followed by steaming off to remove the residual solvent.

Each of these classes of raw material was submitted to the following treatment:—Degreased if necessary; kiered with a completely causticised 3% NaOH solution at 40 lb. for 10 hours, the propor-

D 25, E 25, F 5, G 5, and with this blend the following samples were prepared, the treatment given being that described above unless otherwise specified.

When the specification tests of these samples were known, a suitable treatment was applied to a uniform blend of cotton of the composition given above, and from the resulting product the following samples were prepared:—No. 27, no bleaching or souring; 28, bleached with 0·1% available free chlorine solution, soured with 0·5% acid solution, and thoroughly washed; 29, unbleached but soured with 0·5% acid solution (weaker if possible) and thoroughly washed.

The specification tests were carried out according to standard methods.

The following tables show the results of tests:—

Samples A, B, E, and F were nitrated for manufacturing trials.

For the soda boil a uniform blend was prepared of the following composition:—A 10, B 15, C 15,

The viscosity results of samples B, C, D, E, F, and G were abnormal, and on investigation it was found that the steam pressure during the soda boiling had been too low owing to the position of the gauge on the steam supply pipe. A standard gauge was fitted to the lid of the kier and the temperature in the kier was determined by the introduction of tubes containing organic substances of known m.p. The correct pressure was then maintained and the boils repeated.

The only point of interest in the tests of the samples prepared from the individual raw materials A to G is the apparent ease of reduction of the size of the molecular aggregate in the case of the samples of sweeps and cops compared with the reduction in the case of the samples of fly. The viscosities of the materials before treatment are only approximate owing to the impurities in the samples. From the tests of the samples prepared from the blends 9—26 of the raw materials the removal of the oils is more complete with higher temperature and stronger alkaline solutions and is not affected by extending the time of the boil over ten hours. The ash content is not affected by the conditions of kieriing, but the copper number appears to be slightly reduced with the higher temperature of boiling. Pressure of kieriing up to 40 lb. does not appear to affect the yield to any extent.

The results given for viscosity are the mean of several determinations. The individual tests shown in some cases give different results, due probably to the difficulty of sampling a blend of materials

each having different viscosities. These results are shown in Graph I. below.

- GRAPH I.
- I. Atmospheric, 4% NaOH.
 - II. Atmospheric, 2% NaOH + 2.65% Na₂CO₃.
 - III. 20 lb. .. 2% NaOH.
 - IV. 20 lb. .. 4% NaOH.
 - V. 20 lb. .. 2% NaOH + 2.65% Na₂CO₃.
 - VI. 40 lb. .. 4% NaOH.
 - VII. 40 lb. .. 2% NaOH + 2.65% Na₂CO₃.
 - VIII. 40 lb. .. 1% NaOH + 4.0% Na₂CO₃.
 - IX. 40 lb. .. 2% NaOH.

These graphs clearly show the effect of the concentration of caustic soda, the temperature and the time of boiling on the viscosity of the resultant cotton.

From these results it was impossible to choose conditions for kieriing at 20 lb. pressure which could be relied upon to give a regular product equal to that of a suitable 40 lb. boil. The irregular results given by the 20 lb. boils were thought to be due to the different effects of the boils on each constituent of the blend, some of the constituents being very incompletely broken down. Repeat boils were, therefore, carried out, but the results were again quite irregular, a rise in viscosity after an initial fall during the boiling again being shown. This unexpected development seemed to be well confirmed in spite of every precaution, and it was decided to investigate more closely the change in viscosity during the progress of boiling at 20 lb. pressure. The following programme of experiments was accordingly carried out:—

Series II.

The same blend of raw materials was used as in the first series of tests, but the materials were taken

from different consignments; also the three types of spinners' sweeps were degreased before kieriing, otherwise the conditions and methods for carrying out the boils and the finishing treatments were as before. Table III. gives the results obtained under varying conditions of treatment:—

The changes in strength of solution were very similar for each boil. From the figures it appeared that the total alkali fell by a fairly constant amount during the period of bringing the temperature to a set figure and the first hour of the boil. Throughout the remainder of the boil it remained fairly constant in each case. The initial reduction in strength was due mainly to the dilution of the solution by the condensation of the steam, and to a very small extent only to neutralisation by the impurities in the cotton. Up to the end of the first hour's boiling the strength of the caustic soda decreased and the sodium carbonate increased by a fairly constant amount. Allowing for the amount of dilution determined from the value for total alkali, the loss in caustic soda was approximately equal to the gain in sodium carbonate. Under existing working conditions with unlagged kiers the actual conditions throughout the kier cycle have been roughly calculated and the results are given in Table IV.:—

TABLE IV.

Expt No	Pressure lb	From start to end of first hour.				From end of first hour to end of 20th hour.			
		Ratio. Solution: cotton.	NaOH, %	Na ₂ CO ₃ as NaOH, %	Total as NaOH, %	Ratio. Solution: cotton.	NaOH, %	Na ₂ CO ₃ as NaOH, %	Total as NaOH, %

To ensure the presence of free caustic soda throughout the boil it is, therefore, necessary under present conditions and with the raw materials used to use a solution, the initial strength of which is not less than 3% NaOH. With the exception of the ash content the specification tests call for no comment. The figures for the ash content are slightly above the specification limit, but for economy in production and to save plant costs a series of experiments was carried out to examine as to the possibility of omitting the souring treatment altogether.

It was found that at those mills possessing plant by which the kierung liquor could be prepared from soda ash and lime separately from the kier instead of adding both soda ash and lime to the cotton in the kier, and by paying greater attention to mechanical treatment, the ash content of the purified unbleached unsoured cotton could be reduced to less than 1% which included approximately 0.20% of Na_2CO_3 formed from sodium hydroxide retained by adsorption by the cotton. Consequently permission was given to omit the souring treatment, thus removing also a possible source of objection if traces of acid were left in the purified cotton. The viscosities given in Table III. are plotted in Graph II. below:—

GRAPH II.

I. 20 lb., 4% NaOH. III. 20 lb., 5% NaOH.
II. 40 lb., 3% NaOH. IV. 20 lb., 3% NaOH.

The irregularities in the curves are probably due to the mixed nature of the materials boiled. The effect of boiling on the viscosity of each constituent of the blend was investigated by the Research Department, Woolwich, in the laboratory. The results confirmed previous large scale results from the first series of experiments indicating that the cellulose in materials of the nature of fly is more resistant to the action of alkali, other things being equal, than cellulose in normal cotton fibres.

The composition of the alkaline liquor after kierung has been carefully investigated by Dr. Denham. The full report of this work will be published later, but it is of interest to note that he finds that no decomposition of the cellulose occurred during boiling, that recovery from the liquor of any substances other than alkali was not practicable, and that the liquors could not be rendered suitable for re-use by filtration, though by subsequent work, when purer raw materials, i.e., sliver cotton, were used, the latter method was applied profitably.

In addition to the stoppage of souring referred to above, tests were carried out on samples of treated cotton from the mills to ascertain if the mild bleaching treatment given to the materials boiled at 20 lb. (or under) steam pressure affected

the viscosity of the cellulose. Table V. gives the results obtained.

TABLE V.

Sample no.	Viscosity.	
	Bleached.	Unbleached.
1	6.4	7.3
2	7.5	8.2
3	7.3	8.4
4	41.0	43.0
5	35.0	55.0
6	26.0	21.0

The viscosities having been reduced so considerably by the soda boil, the mild bleaching treatment carried out by the circulation of the cold bleaching solution was without appreciable effect on the viscosity and, as the colour of the cotton was of no consequence to the manufacture of propellants, the bleaching operation was omitted.

When this stage had been reached in the experimental work, circumstances had arisen whereby it was desirable to ascertain the most suitable conditions for boiling at 80 lb. steam pressure. A series of experiments was therefore carried out with a blend of American sweeps 10, Eastern sweeps 10, American willowed fly 35, Eastern card fly 35, American cops 5, Eastern cops 5%, 9000 lb. being used for each boil, and an initial proportion of 4 to 1 of completely causticised 3% NaOH solution.

In carrying out these tests the conditions were as in Series I with one important exception: namely that the steam supply pipes fitted to the kiers were small, in consequence of which the times taken for bringing the contents of the kier to the required temperature were very long. The times of the boils cannot therefore be taken to have any significance. After boiling, the cotton was finished according to the standard method, but in the case of Nos. 1 to 4 watering off was done with hot water. The results of the tests are given in Table VI.

TABLE VI.

Sample no.	Steam pressure, lb. per sq. in.	Time of boil, hrs	Viscosity.
1	80	2½	20.1
2	80	5	16.0
3	80	7½	8.4
4	80	10	22.5
5	40	10	27.2

The results for samples 1 to 4 are all lower, as was to be expected, than the standard 40 lb. boil, but conclusions are deferred until the later section in which the results of nitro-cotton and cordite manufacture are considered together. The two series of samples were subjected to Barrett's test with Malachite Green for the detection of ligno-cellulose, oxycellulose, etc. (*cf.* J., 1920, 81 T). Those boiled at 80 lb. pressure contained less dyed materials than samples boiled at 40 lb. pressure. This is important particularly as the blend of raw materials used in these experiments contained larger amounts of fly than the blend used in the earlier programmes. The quantity of seed husk originally present was therefore larger, but was more satisfactorily disintegrated and removed at the higher temperature.

The specification tests were uniformly satisfactory.

The experiments at the waste mulls were carried out by Mr. J. W. Black, of the Propellants Branch, Ministry of Munitions of War; Mr. F. L. Barrett, who represented the Research Department, Wool-

wich; and Mr. A. Pinkerton, Chemist of the British and Foreign Supply Association.

The preparation of the nitrocottons and the cordites was carried out by Messrs. Nobel's Explosives Company, Glasgow, at their Ardeer Factory, and they also followed up the preparation of the cottons at their own cotton waste purification mill. The examination of the nitrocottons and cordites was undertaken by the Research Department, Woolwich.

Preparation and examination of nitrocotton samples.

The nitrocottons were prepared according to the service methods followed at the Ardeer Factory. The cotton was teased, willowed, dried, and nitrated by the displacement process. The time of nitration was one hour. The nitrated cotton was boiled five times (twice for 12 hrs. and three times for 4 hrs.), each commencing with fresh cold alkaline solution containing 0.27% Na_2CO_3 . After boiling the samples were pulped, washed, and centrifuged in the usual way. Samples were taken during the boiling process and samples of the finished nitrocotton were taken from the centrifuged batches. As a control batches were also prepared from service cotton waste.

The results are given in the following tables:—

TABLE VII.
Specification tests.

Sample No.	Cotton.		Nitrocotton.

26	40	98.6	12.13	0.34	Nil

The usual stability tests—Will, Bergmann and Junk—were normal and disclosed no difference between the various samples of nitrocotton.

The results of the specification tests were normal, the important difference between the samples being brought out in the last two columns. The blended cottons boiled at 40 lb. pressure gave nitrocottons slightly low in nitrogen, but these nitrocottons were much more free from unnitrated material than the nitrocottons prepared from cottons boiled at lower temperatures.

Although the stability tests were all normal it cannot be concluded that the different treatments given to the cotton waste do not affect the stability of the nitrocotton. It would appear possible that the same degree of stability might be produced by a shorter stabilising treatment for nitrocotton prepared from some samples of cotton waste than for nitrocotton prepared from other samples.

The determination of the viscosity was carried out by the falling sphere method (*cf.* Gibson and Jacobs, *loc. cit.*) in ether-alcohol solution. It was found necessary to carry out this test under very carefully chosen conditions in order to render the results for different samples comparable. The conditions were established by the Research Department, Woolwich, after considerable work, from which it was demonstrated that an optimum solvent composition, *i.e.*, ratio of ether to alcohol, exists for each nitrocotton (*cf.* Gibson and McCall, *J.*, 1920, 172 r). The nitrocotton dissolved in its optimum solvent gives a minimum viscosity, the variation of the composition of solvent, either by a greater proportion of alcohol to ether or *vice versa*, causing gelation with consequent increasing viscosity, and the degree of gelation increases with time. The optimum solvent is independent of the concentration of the solution, concentration and viscosity being connected, within a certain range, by the formula of Arrhenius, $\log(\text{viscosity}) = \text{constant} \times \text{concentration}$. The composition of the optimum solvent is, however, dependent upon the nitrogen content of the nitrocotton, the ether concentration increasing with increased nitrogen content.

In view of these results it was decided that comparison of viscosities of nitrocottons could only be made when the viscosities were determined for each nitrocotton dissolved in its optimum solvent, other conditions, *i.e.*, temperature and concentration, being equal. As the object of the whole of this work was a reduction in the consumption of solvent in propellant manufacture, it was advisable in manufacture to use the optimum composition as far as possible if the viscosity of the nitrocotton affected solvent consumption.

Hitherto acetone had been adopted almost universally as the best solvent in which to determine the viscosity of nitrocellulose, although in 1918 Messrs. Du Pont, of the United States, had changed from this solvent to ether-alcohol. It was there-

fore desirable to ascertain if the results given by solutions in acetone were comparable with those given by ether-alcohol solutions, ether-alcohol being used in the manufacture of cordite R.D.B. From the work done a direct relationship was established, and it was found that acetone-water solvent gave gelation results similar to ether-alcohol, the optimum solvent containing about 7% of water (*cf.* Masson and McCall, *Chem. Soc. Trans.*, 1920, 117, 819). From these investigations it was decided to adopt ether-alcohol as the solvent to be used in this work.

Whether the viscosity of the nitrocotton would bear any direct relationship to the viscosity of the nitrocotton-nitroglycerin dough and thus to solvent consumption, required further investigation. It was found that for solutions in ether-alcohol of nitrocotton and nitroglycerin in the proportions in which they are used in cordite R.B.D. manufacture, the optimum composition of the solvent remained the same as if nitroglycerin were absent (*cf.* Gibson and McCall, *J.*, 1920, 172 τ). The viscosity was, however, higher than for the corresponding solution of nitrocotton, but it was approximately equal to that of the nitrocotton solution if in determining the concentration nitrocotton and solvent alone were considered, disregarding the nitroglycerin present. It therefore appeared that the direct determination of the viscosity of nitrocottons alone in ether-alcohol would give satisfactory results for establishing any relationship between viscosity and solvent consumption which might exist.

The results of the examination of the nitrocotton samples from Series III. are given in the following tables, special attention having been directed to the examination of the change in viscosity and stability of the nitrocotton during the boiling treatment.

ture at which the cotton is kiered the lower the content of organic matter insoluble in acetone in the resultant nitrocotton.

The stability results given in Table X. show that the finished nitrocottons have all been reduced to conditions of equal stability. The process samples permit of no differentiation as regards the different treatments of the cotton, but as far as the Bergmann and Junk test may be taken as a reliable indication of stability, relatively little change occurs in the stability of the nitrocottons after the first four-hour boil.

Following the remarks made on the results from the experiments of Series I. as to the effect of the stabilising treatment on the viscosity, the results given in Table XI. are of importance, and have been plotted in Graph III., below.

GRAPH III.

Effect of boiling nitrocotton on its viscosity.

From this graph it is clearly indicated:—(1) That the full boiling process is effective in reducing to comparatively small proportions the initial large differences in viscosity of the various samples. (2) That reduction in viscosity is more readily effected in nitrocotton prepared from cotton boiled with caustic soda at high temperatures than at low temperatures. (3) That the viscosity is reduced to a practically constant figure after a given period of boiling. (4) That the reduction in viscosity to this constant figure is approximately directly proportional to the time of boiling and is not influenced by the quantity of acid present in the water during the boil. This is clear from the reduction in vis-

The conclusion under (2) is important, as if stabilisation could be effected in a shorter time of boiling than is at present followed, the cotton from which the nitrocotton is prepared should be boiled at a high temperature.

The viscosity of the finished nitrocottons prepared from cotton wastes boiled at 80 lb. steam pressure are lower than those prepared from cotton wastes boiled at lower pressures.

Preparation and examination of cordite samples.

Nitroglycerin was added to the nitrocottons in the proportions of 52 to 42, and the mixture was hand-mixed, sieved, and incorporated in the usual way

in a closed mixing machine, the full quantities of ether and alcohol (1.4 pts. ether to 1 pt. alcohol) being added to the mixture in this machine. After mixing had continued for the normal time the dough was transferred to presses and pressed through dies by hydraulic pressure into cords (size 16). The routine observations made during manufacture called for no comment. The following table gives the classification made by Messrs. Nobel's as to the minimum solvent required by each sample to give a satisfactory, good, clear, and smooth cord. The full results of the stability tests of the samples of cordite with and without mineral jelly are not yet available, the initial stability tests not having been included, as they were all normal and showed no difference between the samples.

The results of these trials clearly showed that a reduction in solvent consumption could be effected by the use of a properly prepared cotton waste. The production of cordite R.D.B. varied between 1000 and 1400 tons per week throughout 1918. During this period the conditions for recovery of solvent underwent considerable improvement, but, taking the conditions existing at the time at which these results became available, the application of the results to manufacture would have resulted in a net reduction in the consumption of solvent of 80 tons of ether and 36 tons of alcohol per week, at an approximate value of £11,000.

The results actually obtained in manufacture and the consideration of the relation of solvent consumption to the viscosities of the nitrocotton and the cotton waste are further considered in the summary below.

The results given by the manufacture of cordite R.B.D. from the samples of cotton waste prepared under Series III. indicated that no further reduction in the quantity of solvent required would be possible, but the trials cannot be accepted as final.

Consideration of experimental results.

It is convenient, in considering the results given above, to subdivide this section as follows:—

(a) Empirical relations; (b) viscosity relations. The conclusions are subject to possible modification later, when the results of the stability tests of the cordite become available.

(a) *Empirical relations:*

To determine the most suitable of the treatments given to the various samples of cotton waste from the point view of economy of solvent in cordite R.D.B. manufacture, the following table has been prepared, the samples being arranged in order of merit. The conditions of manufacture of the nitro-cotton were service in each instance, so that reference to the intermediate nitro-cotton stage has been excluded from the table. The effect of the boiling treatment on the nitro-cotton is of the same nature as the effect of the soda boiling treatment on the cotton.

TABLE XIV.

65-6	20	20	4-0	—	16

From this table it is clear that cotton wastes boiled at atmospheric and at 20 lb. pressure do not give the most satisfactory results even when the length of the boil and the concentration of the soda solution are increased. At 40 lb. pressure the samples from the individual raw materials and from the blend were satisfactory, independently of the time of boil and the concentration of alkali. Economically a ten-hour boil with the smallest quantity of caustic soda is to be preferred, but with the necessity of freeing the waste from ligneous matter it is not advisable to reduce the concentration of caustic soda below 3% at any rate for the class of raw materials which were used. It is important for the latter reason also to emphasise the necessity of a drastic soda boil in order to ensure uniformity.

(b) *Viscosity relations:*

The most suitable treatment for cotton waste can be laid down from the preceding section. As a check upon the treatment and to ensure at the mill the issue of a satisfactory product the practicability of adopting the viscosity test and fixing the maximum for viscosity is considered in the following table.

From these results it is seen that there is generally a qualitative agreement between viscosity of cotton, viscosity of nitro-cotton, and solvent consumption. On the other hand the individual results are very variable. Under simpler conditions of production, *e.g.*, the use of one class only of raw material and standard treatment, the qualitative agreement now established might be more definite. Further observations as a matter of

routine at the mills and at the propellant factories should, however, be made.

From this point of view it is of interest to study the relationships through viscosity step by step.

Raw and purified cotton.—The determination of the viscosity of the raw cotton or cotton waste is attended with considerable difficulty. The results given in Table II., samples Nos. A to G, show that in different samples the cellulose molecular aggregate is widely different and different types of cotton are differently affected by the kiering treatment. This is seen in comparing the initial and final viscosities of cotton cops and flys when each is subjected to the same kier treatment.

The temperature of this treatment is the most important factor in reducing the viscosity, while reduction is accelerated by caustic soda and by duration of the treatment. It has not been found possible to determine an equation showing the relation between the viscosity and the temperature, time, and alkalinity of the boiling, but for the economical production of a purified cotton of the lowest viscosity and to ensure uniformity it is necessary to adopt a high temperature boil for the minimum time and with the minimum concentration of caustic soda.

Purified cotton and nitro-cotton.—The relationship between the viscosities of the cottons and of the finished nitro-cottons was carefully considered with the Research Department, Woolwich. The effect of the boiling treatment of nitro-cotton on its viscosity during the boiling, as shown in Graph III., has been already considered. In passing through each stage of the conversion from raw cotton to finished nitro-cotton the cellulose undergoes progressive changes. Assuming that initially the cotton contains cellulose in different highly associated states, changes occur during the boiling of cotton, the rate of change being dependent chiefly on temperature, which results in producing a definite degree of dissociation which does not change under atmospheric conditions of temperature and humidity. Ultimately a state of dissociation is reached beyond which any further dissociation is not possible without disintegration of the

cellulose. The products of nitration prepared under exactly similar conditions from cellulose in different stages of dissociation retain their colloidal nature and may then be related to each other by their viscosities, given that the nitrogen contents of the nitrocottons are the same. The process of nitration, however, as well as introducing ONO_2 groups may affect the degree of dissociation, partly depending on the state of the cellulose initially. The nitration products can undergo by boiling further dissociation, the extent depending also on the degree of dissociation of the celluloses from which they were prepared. Ultimately a definite stage is reached beyond which dissociation measured by viscosity cannot be reduced without decomposition of the nitrocellulose. Plotting then the ratios, viscosities of finished nitrocottons ÷ viscosities of purified cottons, against the viscosities of the purified cottons, Dr. Masson, of the Research Department, Woolwich, obtained the curves given in Graph IV. below:

GRAPH IV.

- I. Cotton boiled at atmospheric pressure.
 II. " " " 20 lb. " "
 III. " " " 40 lb. " "

With the exception of the three points for No. 16, F, and E, all the points lie on regular curves, each curve being distinct for the temperature at which the cotton was boiled. A definite viscosity relationship thus appears to be possible between cotton and nitrocotton when all the factors contributing to the changes are taken into account. Initial differences in the viscosities of purified cottons are minimised on conversion into nitrocottons if the nitrocottons are given drastic boiling treatments. For a nitrocotton of minimum viscosity it is obviously most satisfactory to produce a cotton of low viscosity and so reduce to a minimum subsequent treatments of the nitrocotton. This becomes essential in certain industries in which the nitrocotton used does not require to be boiled unless for viscosity reasons. To obtain nitrocottons of higher or intermediate viscosity a study of the viscosities of the cottons is clearly necessary.

Nitrocotton and cordite manufacture.—A qualitative agreement is apparent from Table XV. between the solvent required for satisfactory manufacture and the viscosities of the nitrocottons contained in the cordite. It is necessary to take the average values for viscosities of groups of nitrocottons, the groups depending on the solvent

required. Individual results are not reliable, and further work is required to establish relations between the concentration of solution used in the laboratory determinations of viscosity with the solution and the consistency of cordite dough. That such relations exist would seem to be clear when the close relation between the curves in Graph IV., the solvent required in cordite manufacture, and the temperature of boiling the cotton is considered.

These results, while not definitely establishing viscosity determinations of the purified cellulose as a means of determining the suitability of the cellulose for cordite manufacture, have established to a large extent the most suitable treatments to be given to cellulose raw materials. Certain relationships have also been established as to the effect of treatments of the cellulose on its viscosity, effect of treatment of the nitrocellulose on its viscosity, and between the viscosities of cellulose and nitrocellulose.

Results from the manufacture of cordite R.D.B.

The results of the experimental work as they became available were applied to the methods of the preparation of the cotton at the mills, and with the cotton then prepared to the manufacture of nitrocotton and cordite R.D.B. at Messrs. Nobel's factories and at H.M. Factory, Gretna.

The method of preparation ultimately instituted at the mills fixed the preliminary picking and degreasing treatments necessary for certain raw materials, the blending of the materials in the proper proportions when charging the kiers, and the proper kier treatment, followed by washing, drying, and the usual mechanical treatments without either bleaching or souring.

The kierung treatment was the essential factor in determining the quality of the resultant cotton, and it was accordingly laid down that after the correct blended quantity of known weight of the cellulose materials had been charged into the kier, 30% NaOH solution, fully causticised and settled, was to be run into the kier in the proportion by weight of four parts of solution to one of cotton. Before closing the kier the air in it was to be displaced by steam, the kier then closed and the contents subjected to a boil at 40 lb. steam pressure for ten hours, the kier being slowly rotated. The hot alkaline liquor was then blown off and the cotton discharged. As the cotton issued from the kier it was immediately "drowned" by adequate sprays of cold water, so that oxidation should not take place.

Some time was taken in obtaining the necessary conditions at the mills to ensure that the treatment was followed. At each mill a technical staff was placed and scientific methods were then adopted in operating the mills. These methods covered studies of capacity of plant in relation to production of materials, efficiency, including steam production, and monthly process costing. The complete re-organisation was effected by June 1, 1918, and through the efforts of the new staff the average total cost of production fell month by month, until in October, 1918, a reduction of £13 per ton had been effected, making the comparison on an equal basis with the average total cost for the six months ending March 31, 1918.

The products supplied to Messrs. Nobel's, who used them admixed with materials of their own manufacture, also prepared according to the above method, and to Gretna, enabled these factories, the total production of which was some 800 tons of cordite R.D.B. per week, to reduce the mixed solvents they used for incorporation by 11% and 7½% respectively on the previous figure of 65 parts of solvent per 100 parts of cordite. At the same time the additional uniformity of the purified waste removed some difficulties experienced in the manu-

facture. Substantial confirmation was therefore obtained of the large-scale experimental results. Routine observations of viscosity were made on all the products at the mills, but whereas generally the viscosities were reduced to a low figure there were irregularities in the results which were not eliminated.

Experimental work on the preparation of a cotton cellulose suitable for nitrocellulose powder.

Towards the end of 1916 it was decided to manufacture nitrocellulose powder in this country and to adopt the process used by Messrs. E. I. du Pont de Nemours and Company.

Nitrocellulose powder, consisting almost entirely of nitrocellulose, has for its basic raw material prepared cellulose, generally cotton cellulose. The du Pont process for the manufacture of the powder includes the "dipper" process for the nitration of the prepared cotton, which necessitates the use of cotton of very short fibre, much shorter than the fibre of the bulk of the raw materials used in the preparation of cotton waste for the manufacture of nitrocotton for cordite R.D.B.

Representatives of the du Pont Company emphasised the importance of the nitrocellulose possessing certain physical and chemical properties, among which were:—(1) A low viscosity in acetone or ether-alcohol with, for cannon soluble nitrocellulose, the highest possible solubility in the latter solvent, to give an easy-flowing colloid and consequently low solvent consumption in manufacture. (2) A satisfactory stability, especially for high-grade nitrocellulose used for rifle nitrocellulose powder and containing 13.1–13.3% of nitrogen.

With regard to (1) the du Pont Company used as their raw material a mixture of cotton hull shavings and cotton linters of very short fibre, both of which qualities were highly contaminated with lignocellulose. Their representatives emphasised also the necessity of a drastic soda boil such as they had adopted, namely, 80 lb. steam pressure for 5 hours, to give a satisfactory and uniform product. Du Pont's determined the quality by making large scale trials of representative samples of new lots of purified material.

With regard to (2), the stability of the nitrocellulose powder partly depends on the purity of the cotton used, i.e., on its freedom from lignocellulose etc. The quality of the raw materials used by the du Pont Company necessitated a treatment which would break down these compound celluloses. This it was found was effected by a drastic soda boil, and thus the requirements under this head and under (1) were met by the one operation.

The manufacture of the nitrocellulose powder in this country was eventually undertaken at H.M. Factory, Irvine, erected and operated by Messrs. Nobel's Explosives Company. The Director of Propellant Supplies decided that the stock of raw linters, of a higher grade than those used by du Pont, in this country should be used for Irvine, and the purification of them to meet Irvine's requirements should be carried out at one of H.M. cotton waste mills.

When work commenced to ascertain a suitable treatment for the raw linters much of the experimental work on cotton waste for cordite R.D.B. had been done, and the results therefrom agreed with the experience of Messrs. du Pont.

Nitrocellulose powder being a new manufacture to this country, to be carried out in a newly erected factory as sections of it became available, no programme of experimental work such as that given in the foregoing report could be done. After preliminary trials, the results of which, owing to the conditions of manufacture, could not be taken as

more than indicative, series of large-scale experiments were put in hand under proper conditions at the mill and at Irvine.

Preparation and examination of purified linters.

The conditions of preparation as regards kiering treatment and the results of viscosity tests of the products are given in the following table.

TABLE XVI.

T=time of boil. P=pressure. S=strength of caustic soda solution.

The viscosities, except for the products from the 70-lb. treatment with 2% and 3% caustic soda, show great irregularity and are very high compared with the results obtained under the R.D.B. experimental work in which different raw materials were used. Taking the average values generally, it would appear that increase in temperature of boiling, increase in time of boiling, and increase in strength of the kiering solution each reduces viscosity. This agrees with the results of previous work. The irregularities are partly due to the irregularities in the raw linters, the difficulty of reducing their viscosity, and the difficulty of obtaining a satisfactory cuprammonium solution of material having a high viscosity. As is well known, the cuticular substance of the cotton fibre can be separated from the inter-cuticular by solution in Schweitzer's reagent, and it would seem that linters contain a relatively high proportion of cuticular cellulose which, being much more resistant to conditions influencing physical change, may be expected to cause a high viscosity. Unless completely broken down, the presence of this material may cause irregularities in the nitrocotton and incomplete gelatinisation in the powder. Further information which points to the same conclusion as regard the cuticular cellulose is given below from actual manufacturing evidence.

The products from raw linters boiled at 70 lb. pressure with 3% caustic soda solution give regular results comparable with those given by the du Pont sample of cotton and lower than those obtained by the standard treatment for R.D.B. materials. The cuprammonium solutions were also quite satisfactory and lignocellulose from the seed husk etc. was practically decomposed, which was not the case with the material from the 70 lb. 2% solution boils.

From these results, and as it was not possible with the plant available to increase the pressure beyond 70 lb., this pressure was ultimately adopted for manufacture. Throughout manufacture viscosity determinations were carried out for each batch of the material produced, the total production amounting to some 2000 tons. Of the part of this which was given the standard treatment finally adopted, a proportion was boiled for ten hours and the remainder for six hours. A summary of vis-

the cellulose in it was decomposed. The effect of this decomposition on the yield is indicated in Table XVIII. The difference in yield shown between March-May period and the October-November figures was due to greater efficiency in the purification process. This efficiency was also increasing throughout the June-September period. The effect of the use of partly disintegrated material on the viscosity of the product is also shown in Table XVII. From this table and foregoing remarks it

would seem probable that the decomposition of the cuticular cellulose takes place much more slowly.

Preparation and examination of the nitrocottons.

The nitrocottons prepared from which results are available were pyronitrocelluloses for cannon powders. They were completely soluble in ether-alcohol and contained 12.50—12.60% nitrogen. For stabilisation the boiling treatment given was one 24-hour and four 2-hour boils with water. Of the experimental batches of cotton prepared only A3, B2, B3, G1, G2, and G3 (see Table XVI.) were fully examined. The results, together with a few others from manufacturing records, are given in the following table:—

Cotton treatment.—P=Pressure and T=Time of soda boil.

cosity tests is given in Table XVII. During the production of this quantity a stock of raw materials which had been lying exposed to the weather had to be taken into manufacture as quickly as possible, as, owing to bacterial action, a large proportion of

The conclusions drawn from Graph III, are confirmed by these additional results. The effect of the first boil of 24 hours on the viscosity of nitrocotton from linters is very similar to that of the two 12-hour boils on nitrocotton from R.D.B.

cotton, though in the former case there is no intermediate stage to confirm that the fall in viscosity is regular. The changes in viscosity of cellulose and nitrocellulose are essentially dependent on temperature conditions whether in the kieren of the cotton or in the nitration and stabilising processes of the nitrocotton. From this arises a point which requires further investigation and may be the cause of the slight irregularity in the results now given, namely, the effect of the hot water in contact with nitrocotton during the period of raising the contents of a boiling vat to 100° C. and during the period of running off the hot water.

Conclusion 2 from Graph III. is also confirmed by these further results, and, as will be seen later, this is of even greater importance in the manufacture of nitrocellulose powder than in the manufacture of cordite R.D.B.

Taking the mean values for the viscosity of cotton and plotting these against the ratio, viscosity of finished nitrocotton ÷ viscosity of cotton, the curve in Graph V., below, is obtained.

GRAPH V.

This curve is again similar to those given in Graph IV., but owing to the cottons in this series of experiments being boiled at different temperatures and also owing to the irregularity of their viscosities, the points lie less regularly on the curve. The latter may, however, be taken as sufficiently regular to confirm the previous conclusions, that there is a definite relationship between the viscosity of the cotton and the ultimate viscosity of the nitrocotton prepared from it. The curves generally appear to be of the form:

$$\eta_c = K.10^{(1 - \eta_n/c \div \eta_c)}$$

where η_c is the viscosity of cotton and η_n/c that of finished nitrocotton, and K a constant for each curve. Substituting the values for η_c and for η_n/c the values for $\log K$ obtained from this equation for the R.D.B. nitrocottons under Series I. and III. and for the N.C.T. nitrocottons are given in the following table.

The differences between the values of $\log K$ for Series III. and those for Series I. and linters are due to the difference in the concentration of the solution for determining η_n/c .

Obviously the conditions under which these experiments are carried out and the materials used cannot be expected to give accurate values for K , but even so there would seem sufficient indication that K would be found to be constant if carefully controlled experiments were done in the laboratory.

Manufacture of nitrocellulose powder.

Manufacture of "cannon nitrocellulose powder" at Irvine was for some time too beset with mechanical difficulties to allow any conclusions to be safely drawn as to the effect of the viscosity of the nitrocotton used upon the solvent required for pressing the nitrocotton-ether-alcohol dough. These difficulties were overcome, but when manufacture stopped after the Armistice it had not progressed sufficiently to enable final conclusions to be drawn. The results which were obtained from the carefully controlled manufacture of nitrocellulose powder from the experimental lots of cotton are given in the following table:—

Messrs. Nobel's comments on the manufacture of these lots were that: (1) Service batch 1, even with the larger quantity of solvent still required higher pressure and was unsatisfactory. (2) A3, B2, and B3 with the additional solvent pressed normally, but the trials were less satisfactory than was desired. (3) In dehydration the nitrocotton from G1, G2, and G3 showed considerable superiority over any previous lots. The dough from G1 when pressed gave particularly good cords of size 16 cannon powder at an average gauge pressure of 2700 lb. G2 and G3 were not quite so satisfactory as G1. Results with the special lot were similar to G1, using 106.5% of solvent. A gauge pressure of 2400–3000 lb. was used in pressing, and clean cords with extremely smooth surfaces were produced. The quality of the powder was in all respects equal to that produced at Irvine from du Pont nitrocotton.

From these results, as in the case of cordite R.D.B. manufacture, the temperature at which the cotton is kieren affects the viscosity of the purified cotton, the viscosity of the unstabilised nitrocotton and the ease of reduction in this viscosity during the boiling treatment, the viscosity of the finished nitrocotton, and most directly the pressing of the powder and the quantity of solvent required.

It is obviously desirable that the cotton should be boiled at least 70 lb. pressure with 3.0% caustic soda solution. If this be done the viscosity may

generally be reduced to below 25 C.G.S. units. In the foregoing tables instances are given where this has not been the case, and viscosities of over 100 even with the boiling pressure of 70 lb. have been obtained. No powder manufacturing trials have been done with such material, but it may reasonably be expected from all the evidence given that they would not be as satisfactory as those from cotton boiled at a high pressure and having a viscosity lower than 25 C.G.S. units.

The results from this work are therefore generally in agreement with and confirm those obtained from the cordite R.D.B. investigations.

literature to guide the work, taken comprehensively as a whole, and the necessity of devising methods of testing which have still to be perfected, render quantitative detailed conclusions impossible. On points of minor importance the deductions from the results, if not already drawn in the report itself, may readily be made:—

(a) The cellulose contained in different raw cotton cellulose materials has very different viscosities, and even in the same fibre the cellulose is probably in different states of molecular aggregation which may vary with the age or growth of the cotton.

Conclusion.

Up to the present, the viscosity of cellulose, and more particularly that of its derivatives for their subsequent application, has in those industries in which it has played any part chiefly been dealt with as a specific property, certain values for which have to be obtained, rather than as a specific property depending basically on the constitution of cellulose itself. This is seen in the numerous patents which continue to be taken out, *e.g.*, in the manufacture of suitable varnishes, lacquers, and dopes, depending on empirical efforts to achieve the desired object, and thus helping, but very inconsiderably, the scientific study of the constitution of cellulose, its properties as a typical colloid substance, and the reason therefore of such properties and their changes under different conditions.

This has been particularly the case in the nitrocellulose industry. W. Will (Z. angew. Chem., 1919, 32, 133; *cf.* J. J., 1919, 479 A) has recently mentioned the same difficulties in the determination of viscosities as were encountered in this work, but could trace finally no relationship between the viscosity of the cellulose and the properties of the nitrocotton prepared from it. Further, it was concluded that conditions in the manufacture of propellant powders were more dependent on other properties than on viscosity. Attention may also be called to references in the publications of the Department of Scientific and Industrial Research on Colloid Chemistry for 1917 and 1918.

It has already been stated in Cross and Bevan in *Researches on Cellulose*, 1900–1905, that the colloidal properties of cellulose are retained and determine the properties of its derivatives obtained by chemical treatment, the example given being viscose. The importance of this to the viscose artificial silk manufacture is pointed out, and in artificial silk manufacture by the different processes, the viscosity question, chiefly of the derivatives of cellulose, has had the most important attention from the industrial point of view.

The conclusions drawn from the work under report must be essentially ones of general principle, as the lack of any earlier experimental evidence in

(b) In the purification treatment given to the cotton cellulose, the essential treatment effecting change in the cellulose is the boiling with caustic soda. The reduction in the molecular aggregate of the cellulose can be effected by heat alone, but it is accelerated by the presence of water, and more so by the presence in the water of sodium hydroxide. The changes in different raw celluloses are effected at different rates, but ultimately, if the treatment be sufficiently drastic (the temperature to which the cotton is subjected being the essential factor), the product from all sources of cotton is essentially the same, beyond which further changes may possibly be only effected by chemical changes. The products consist of normal resistant cellulose retaining its properties as a colloid.

(c) The cellulose aggregate retains its properties as a colloid throughout nitration, and governs the colloidal properties of the ester. The introduction of nitro groups into the cellulose aggregate may or may not change the aggregate, according to the conditions of nitration, but they render it capable of further modification, depending on the cellulose aggregate, and again brought about by heating the nitrocotton at different temperatures, the change being accelerated by the presence of water. Ultimately, as in the case of cellulose, the product undergoes no further change unless accompanied also by chemical change.

From the graphs showing the changes of nitrocelluloses during the boiling process the product reached in each case would seem to be an ultimate nitrocellulose.

The relation between the viscosity of the ultimate nitrocellulose from each cotton and the viscosity of the cellulose from which it was prepared is definite, so that for nitrocotton of desired viscosity the nature of the raw cellulose and the treatments to be given to it and to the nitrocotton can be determined.

(d) The properties of the “gel” formed from nitrocellulose, with or without a gelatiniser, *e.g.*, nitroglycerin, by means of solvents of the nitrocellulose, depend essentially on the physical properties of the nitrocellulose. The properties of the “gel”

determine methods and conditions of manufacture and the properties of the finished product. A qualitative agreement only has been established so far between the viscosity of the nitrocellulose and the solvent required for its satisfactory conversion into propellant powders. This qualitative relationship is of practical value, and under more accurate conditions of determination (than obtains actually in propellant powder manufacture) of the solvent required the relationship might be shown to be quantitative. The concentration of the nitrocellulose solvent "solution" during pressing of the dough is approximately 60%. For solutions of lower concentration such as obtain in other manufactures, the relation between the viscosity of a 5% solution of nitrocellulose in ether-alcohol and the quantity of solvent required in manufacture, other conditions being equal, should be more readily obtainable. It is to be understood that the solvent required in manufacture is of the optimum composition.

(e) The results of the stability trials and of the examination of the degree of gelatinisation of the powders are not yet available and, beyond general observations in manufacture, no direct tests were carried out to trace the relationship through viscosity to the other physical properties of the finished products.

(f) Other conditions being equal, i.e., the intermediate stages in manufacture, the operations in the conversion of the nitrated derivatives of cellulose into finished product, which depend on the colloidal nature of the derivative, are directly influenced by the properties of the cellulose as a colloid from which the derivatives are prepared. This influence may be traced through viscosity measurements, but a more direct relationship is apparent between the operations and the temperature to which the cellulose has been subjected in the purification treatment of the raw material. From a practical point of view, to produce the finished product as economically as possible and having the desired properties, the nature of the raw cellulosic material and the treatment given to it in purification are the fundamental factors. Subsequent operations may then be simplified and, combined with the treatment of the raw cellulose, any required properties in the derivative may be obtained.

(g) It is now perhaps permissible to infer generally that in the production of any article having cellulose as its essential base and depending on colloidal properties the above conclusions apply to a more or less greater extent.

In these conclusions some references have been made to the nature of the changes in the cellulose aggregates which lead to further considerations of the constitution of cellulose. The cellulose aggregates in nature vary widely, but they may be reduced by the action of heat, ultimate degrees of dissociation being reached according to the temperature, without the introduction, however, of any chemical change modifying the configuration in regard to esterification. Nitration may cause association, but it is clear that after nitration the aggregate may be further reduced to an ultimate degree, similarly without causing any chemical change in the nitrocellulose. It may therefore be concluded that the definite configuration of the reacting unit remains constant throughout the various dissociations. It is clear that in further work on these lines to obtain the ultimate cellulose reacting unit, either by comparison through similar groups of esters or by the comparison through different esters, the cellulose used as the starting point should be the same or in the same degree of dissociation, preferably in the lowest state, as deter-

mined by its viscosity in a suitable concentration of cuprammonium solution.

In conclusion the author wishes to express his thanks to Sir F. L. Nathan, Mr. William Macnab, Messrs. Nobel's Explosives Co., Ltd., Dr. W. H. Gibson, Mr. P. Tainsh, and Mr. J. W. Black for the assistance which they have given him in carrying out the work, in compiling the report, and in its publication.

A METAL-GLASS TAP.

BY WILLIAM EDWARD GARNER.

McKelvey and Taylor have recently (*J. Amer. Chem. Soc.*, 1920, 42, 1364) given details of glass-to-metal joints used by the Bureau of Standards, U.S.A. A glass-metal tap of a different type from those described in the above paper has been constructed by the author and used with a mercury-in-glass manometer for the measurement of pressures between 2 and 10 atm. The diagram shows this tap in section. The joint is made between a metal disc, A, and a larger glass disc, B; A is attached

to a steel capillary tube, and B is fused to a glass capillary tube. A hole is drilled centrally through the glass disc and a similar hole drilled obliquely through the metal disc to the interior of the capillary tube. Both discs are placed in brass cells, C and D, which are keyed into one another when in position. The glass disc is fastened centrally into its cell by means of a cement composed of glycerin, litharge, and sodium silicate, and the exposed glass surface is carefully ground. The smaller metal disc can be revolved freely in its cell about an axis parallel to, but not in the same line as the axis of the glass capillary tube. The distance between the two axes is determined by the obliquity of the hole in the metal disc. The glass and steel surfaces are held together by means of a cap, which screws on to C. The metal and glass surfaces are carefully ground in position with fine carborundum, and in order to make a gas-tight joint, rubber grease is used as a lubricant. By revolving the metal surface on the fixed glass surface, the two holes can be

made to coincide (as in the diagram) and connexion established between the gas in the two capillary tubes. This only occurs in one position, and further movement in either direction closes the tap. The tap is opened and closed by means of a strip of metal, E, which is soldered to the steel tube, and the open and closed positions are controlled by a collar and pin, F.

The glass disc may be made by opening out the end of a capillary tube into a funnel and pressing down the hot glass on a strip of asbestos. This method has the advantage of avoiding the necessity for drilling glass which may be in a state of strain.

Chemical Laboratories,

University College, London.

THE DISTRIBUTION OF ENZYMES AND PROTEINS IN THE ENDOSPERM OF THE WHEAT BERRY.

(ADDENDUM.)

BY F. J. MARTIN.

(See J., 1920, 327 T.)

The author has supplied the following note to explain more fully how the various samples of flour were obtained:—

"The wheat was conditioned to the hardness of good average English, and the Humphries process

of spraying stocks was employed. The extraction of flour was about 70—72%.

"In the mill in which the wheat was ground a "Four-break" system is employed, the general principle of which is as follows:—The wheat is passed through the First break and the flour and semolinas (pieces of endosperm) produced are separated out; the remainder, which consists of the broken husk with a large amount of endosperm attached, goes to the Second break where a similar operation is performed. The material that then goes to the Third break has less endosperm attached to the husk, and subsequently the Fourth break removes the last scrapings of endosperm from the bran. The reductions are lettered alphabetically from A . . . N, A, B . . . denoting the highest reductions (*i.e.*, from the beginning of the mill) and . . . M, N the lowest reductions. The semolinas produced from the First break go to the highest and those from the Fourth break to the lowest reductions: the semolinas from the intermediate breaks go to the intermediate reductions.

"Examination of the stocks going to the various reductions shows that the higher reductions are comparatively free from husk, and, therefore, of particles near the cortex, while the lower reductions have a larger proportion of particles with pieces of husk attached, showing that they are derived from near the outside of the berry."

Mixing calculations. A. B. Helbig. Chem.-Zeit., 1919, 43, 786.

THE author gives formulae for calculating the amounts of raw materials, each containing up to four components, required to give a product of definite composition.

PATENTS.

Separating a salt from its solution by evaporation; Process and apparatus for —. P. Piccard, Geneva, Switzerland. Eng. Pat. 132,771, 15.5.19. (Appl. 12,292/19.) Int. Conv., 14.9.18.

IN the method of evaporation where a liquid is heated under pressure without evaporation in reheaters and then evaporated by reduction of pressure in the evaporator proper, the jet of heated liquid entering the evaporator is caused to impinge upon a solid obstruction upon which crystals will be deposited that will be coarser than those formed in a body of comparatively still liquor. The obstruction may preferably take the form of a screen which rotates against a scraper or is fixed and scraped by a rotating scraper.—B. M. V.

Evaporating liquids; Method of and apparatus for —. O. Carr, Asheville, N.C. U.S. Pat. 1,321,362, 11.11.19. Appl., 24.2.15.

A CHAMBER is provided with a horizontal pipe extending longitudinally along the bottom and provided with openings of variable area along its upper side. The openings increase in area towards the end remote from the inlet. Liquid to be evaporated is sprayed horizontally into the chamber above the perforated pipe, and hot air is delivered through the pipe to meet the liquid spray at right angles. The hot-air blast is sufficiently strong to carry the solids and vapour upwards to an outlet pipe at the top.—W. F. F.

Furnaces. H. Wade, London. From Fours et Procédés Mathy Soc. Anon., Liège, Belgium. Eng. Pat. 134,169, 3.5.19. (Appl. 11,113/19.)

A FURNACE is provided with alternative means of firing. A gas producer placed at one end of the furnace allows the use of producer gas, which is mixed with air at the top of the producer before it enters the furnace chamber. An arch built part way across the producer near the top forms a combustion space into which liquid fuel may be injected through the wall of the producer. A flameless combustion burner forms a third alternative, and is arranged by filling a conduit between the producer and furnace with porous refractory material and injecting a mixture of gas and air. Each of these arrangements may be used independently or to assist one another, and heated air may be used for combustion by conveying it from the regenerator to the point of combustion.

—C. A. K.

Furnaces and like apparatus for producing hot air for drying and other purposes. H. Wade, London. From Schlatter, Frorath & Co., Zurich, Switzerland. Eng. Pat. 135,332, 6.12.18. (Appl. 20,298/18.)

SEE U.S. Pat. 1,301,324 of 1919; this J., 1919, 490 A. The filter consists of several superposed layers of broken refractory brick or other fireproof, non-sintering material having catalytic properties, the pieces forming the layers being smaller towards the top. The material is heated to a high temperature, whereby there are effected not only mechanical retention of dust and chemical combustion of sulphur, but also combustion of soot and smoke.

Heating-furnace. B. D. Gray and E. W. Ruben-came, jun., Philadelphia, Pa., Assignors to The Hess-Bright Manufacturing Co. U.S. Pat. 1,321,098, 11.11.19. Appl., 6.3.17.

THE heating chamber is formed longitudinally in the furnace, and is closed at the top and ends. The articles to be heated are inserted transversely into the heating chamber through openings in the wall, and the heating gases are admitted at the rear end of the chamber through a number of vertical pipes terminating near the top of the chamber. The hot gas passes over the articles, and then out through flues leading downward and towards the rear of the chamber.—W. F. F.

Muffle furnace. W. G. Zetsche, Chicago, Ill. U.S. Pat. 1,322,214, 18.11.19. Appl., 28.2.19.

THE furnace casing is provided with fuel-feed inlets at one end, and an outlet for combustion products at the other end. A number of muffles are mounted so as to span the furnace space transversely, with one end projecting through the furnace wall. The muffles are spaced apart and are heated successively by the hot gases. The open end of each muffle is provided with a closing plug, and valve-controlled openings are provided in the furnace walls to admit air for regulating the temperature.—W. F. F.

Shaft kiln with automatic emptying device. G. Polysius, Dessau. Ger. Pat. 314,308, 20.6.16.

A SHAFT kiln is provided with an automatic emptying device and dampers arranged in succession in the discharge shoot so as to form two chambers, the lower one being connected with a fan which blows the dust into a dust chamber or supplies the kiln with air under pressure. The variations in the air pressure in other shaft kilns are avoided, as the outward passage of air under pressure is impossible, and the exhaustor does not draw air directly from the kiln. The use of several dampers also reduces the loss of heat from the kiln, as the heat in the cooling material may be used to warm the ingoing air.—A. B. S.

Air or gas; Apparatus for treating and cooling —. Heenan and Froude, Ltd., and L. Cruyt, Manchester. Eng. Pat. 134,256, 27.8.18. (Appl. 13,905/18.)

METALLIC wool (in which term is included wire, turnings, or any metallic material that will produce a spongy or porous mass) supported between plates of expanded metal, wire gauze, or the like, is built up into screens or drums which are kept wet by means of liquid sprays or by rotating them in a bath of liquid. The blades or vanes of the apparatus described in Eng. Pat. 109,648 (this J., 1917, 1171) may be made of metallic wool held in place, for example, by perforated sheets.—B. M. V.

Air or gases; Apparatus for filtering or otherwise treating —. Heenan and Froude, Ltd., and L. Cruyt, Manchester. Eng. Pat. 134,873, 8.10.18. (Appl. 16,318/18.)

AIR or gas is passed over non-perforated battles placed at an angle to the direction of flow, and formed of or covered with hygroscopic material such as felt, wool, flannel, or the like.—W. F. F.

Solids from gases; Apparatus for removing and reclaiming —. E. J. Sweetland, Montclair, N.J., Assignor to United Filters Corporation. U.S. Pat. 1,321,490, 11.11.19. Appl., 4.8.15.

GAS under pressure containing solids in suspension is passed outward through a tubular filtering member which intercepts the solids. An annular nozzle slides longitudinally on the tubular filter, and a current of gas may be forced from the nozzle

inwards through the filter at successive zones to detach the solid material.—W. F. F.

Drying or heating apparatus of continuous type. Dressler Tunnel Ovens, Ltd., and J. Williamson, Stoke-on-Trent. Eng. Pat. 134,332, 1.11.18. (Appl. 17,895/18.)

THE goods to be heated or dried are moved slowly forward on a carrier through a chamber filled with air heated by a heater situated in another chamber below the first. In the main or middle part of the furnace the heater is preferably heated by the combustion of gas or other fuel inside it, and the main movement of the air which conveys the heat to the goods is upward from the heater, among the goods, and down through side passages to the bottom of the heater, though a small quantity may be drawn off by a chimney or other draught to produce a slow longitudinal movement as well. In the tail end of the furnace the lower chamber may be omitted and air from outside allowed to pass through the goods to cool them, and the air thus preheated used for combustion in and/or circulation round the main part of the furnace. When used as a dryer, an extension at the feed end of the chamber is provided, so that most of the moisture can be removed from the goods at a low temperature. The heater for this part is preferably a nest of tubes carrying the products of combustion from the main heater, while the air which transfers the heat does not circulate, but after rising among the goods passes out of the furnace.—B. M. V.

Dryer. W. E. Prindle, London, Ohio, Assignor to The Buckeye Dryer Co., Columbus, Ohio. U.S. Pat. 1,321,332, 11.11.19. Appl., 30.4.17.

A ROTARY horizontal shell is provided with sets of longitudinal compartments spaced apart lengthwise of the shell. Each compartment has lifting blades, the number of blades increasing towards the discharge end of the shell.—W. F. F.

Cooling liquids; Apparatus for —. J. I. Thornycroft and Co., Ltd., and T. Thornycroft, London. Eng. Pat. 134,271, 21.10.18. (Appl. 17,163/18.)

A COILED double tube (the two tubes having a common axis) is placed in a tank and the liquid to be cooled passes first through the inner tube and then into the tank, which thus can serve as a reservoir for cooled liquid as well as providing additional cooling surface. The cooling liquid, though supplied from and exhausted to the exterior of the tank, is circulated through the outer tube by means of a centrifugal pump contained within the tank. The pump may be driven by external power or by a small turbine wheel which is rotated by the liquid which is being cooled as this passes from the inner tube to the outer tank.—B. M. V.

Refrigerating apparatus. H. Southon, London. Eng. Pat. 134,348, 7.11.18. (Appl. 18,237/18.)

A U-TUBE of fused silica, glass, or similar material is partially filled with dilute sulphuric acid (rather more than half acid by weight), the air is then exhausted, and the tube hermetically sealed. Most of the acid is tilted into one limb of the tube, which is then held substantially horizontal, and the limb containing the acid is gently heated, while the other limb is kept cool. Surface evaporation from the acid takes place (ebullition must not be permitted) causing concentration of the acid in one limb and condensation of water in the other. When the acid is sufficiently concentrated it is cooled, and the consequent absorption of water vapour causes evaporation in the other limb, which will now serve as a refrigerator. In order to prevent formation of ice in this limb, a small quantity of acid is purposely left there.—B. M. V.

Artificial-refrigeration method and apparatus. C. W. Miles, Anderson Township, Ohio. U.S. Pat. 1,321,230, 11.11.19. Appl., 11.11.15.

GAS is withdrawn from the refrigerator at low pressure and then liquefied in a condenser at a higher pressure. The liquefied gas is separated, the lower layer of it is pre-cooled by means of the cold, low-pressure gas from the refrigerator, and is separated from the unliquefied gas by a relatively warmer layer. The pre-cooled liquefied gas is then passed into the refrigerator.—W. F. F.

Retorts and stills. J. Prentice, East Riggs. Eng. Pat. 134,406, 9.12.18. (Appl. 20,447/18.)

A RETORT is made with a detachable bottom which can be removed upwards through the retort without removal of any of the brickwork setting. The lower end of the main body of the retort has an inwardly-directed flange which forms a seat for a corresponding outwardly-directed flange on the bottom of the still. If the bottom is provided with an outlet spout, only a few bricks have to be removed round the spout sufficient to allow the bottom to be tilted before being lifted.—B. M. V.

Distilling apparatus. O. S. Sleeper, Assignor to Buffalo Foundry and Machine Co., Buffalo, N.Y. U.S. Pat. 1,321,133, 11.11.19. Appl., 28.1.18.

THE apparatus comprises a retort, condenser, receiver, and separator, connected in series. The separator comprises a vertical chamber having its inlet and outlet on opposite sides at the top, while a baffle extends vertically downwards from the top between the inlet and outlet, terminating at a point about one-third of the height from the bottom. An outlet is provided at the bottom of the separator and is connected with an exhausting device.—W. F. F.

Filter-press plates. W. O. Mason, Leeds. Eng. Pat. 134,415, 9.12.18. (Appl. 21,231/18.)

A FILTER-PRESS plate consists of a wooden frame fitted with a fluted panel of reinforced glass.—B. M. V.

Mixing liquid, semi-liquid, or viscid materials; Machine for —. A. Sonsthagen, London. Eng. Pat. 134,451, 8.2.19. (Appl. 3117/19.)

IN a mixing machine consisting of a horizontal cylinder with two sets of opposing helical blades, one set of which gives a rather greater forward impulse than the other, the outlet is arranged in such a way that it can be swung in any direction, so that, if desired, the material may be delivered at a higher level than the mixing cylinder, thus causing the material to fill the apparatus completely and exclude all air. When admission of air is desirable the outlet may be swung downwards, air then entering through a slit or series of holes in the top of the cylinder, which may be covered with a perforated or non-perforated cover according to whether air is to be admitted or not.—B. M. V.

Grinding mills; Disc and like —. J. R. Torrance, Bitton. Eng. Pat. 134,618, 5.11.18. (Appl. 18,127/18.)

IN order to prevent scoring and uneven wear of flat discs in grinding mills, the shaft of the rotating disc is journaled in a sleeve, the outer perimeter of which is concentric with the axis of the mill, whilst the inner perimeter is slightly eccentric, so that in addition to the rotation an orbital motion is imparted to the disc. The eccentric sleeve is driven by a worm, which in turn is driven by a pair or train of pinions from the same main shaft that gives the rotary motion to the disc shaft by means of bevel wheels. Since the bevel wheel driving the shaft must be concentric with the mill and eccentric with the shaft, it is provided with internal

slots that engage with external projections on the shaft. When grinding liquid or pasty materials a scraper may be arranged to scrape the edge of the rotating disc by following its lateral but not its rotating movement, or it may be firmly attached to the rotating eccentric sleeve, so as slowly to sweep the annular collecting chamber in the fixed outer casing. In some cases it may be desirable to give a lateral movement to the companion disc, which is usually fixed. The fineness of grinding is regulated by a screw-adjusted lever pressing through a ball thrust bearing on to the end of the disc shaft.

—B. M. V.

Centrifugal extractors. Safety control devices for centrifugal dryers. Centrifugal drying apparatus. L. W. Gould, Birmingham. From American Laundry Machinery Co., Cincinnati, U.S.A. Eng. Pats. (a) 134,654, (n) 134,799, and (c) 134,800, 27.11.18. (Appls. 19,532/18, 18,782/19, and 18,783/19.)

A CENTRIFUGAL extractor is provided with a double basket; the inner basket can be lifted vertically for the easier discharge of the dried goods. A belt driven from an extension of the loose pulley of the machine provides power for lifting and lowering the inner basket by means of suitable gearing. A large non-rotating cover which rises with the inner basket, and a device which can be placed close up to the raised basket and used as table for the dried goods are also provided. To ensure safe operation mechanical interlocks are provided, so that:—(a) The inner basket cannot be raised or lowered when the machine is rotating; (a) the raising and lowering mechanism cannot be operated nor the cover raised unless the brake is on and the driving belt on the loose pulley; the driving belt cannot be put on the fast pulley (for rotation) when either the basket or cover is raised, nor can the inner basket be lifted or lowered when the cover is raised; and the inner basket cannot be lowered without first moving the movable table out of the way; (c) the raising and lowering of the inner basket is restricted within definite limits.

—B. M. V.

Separators; Centrifugal —. R. A. Sturgeon, Southsea. Eng. Pat. 134,966, 22.11.18. (Appl. 19,233/18.)

LIQUID to be treated is supplied through the annular passage, B, to the centrifuge, A, which is provided with a piston, C, adapted to be raised by

the pressure produced by centrifugal force in a liquid admitted below the piston as in Eng. Pat. 24,038/13 (this J., 1915, 263). The cover, D, is normally retained by centrifugal weights, but is lifted when the solid material thrown against the wall, A, exerts sufficient pressure against it. The solid

material is broken up and forced through the annular chamber, F, the inner wall of which, F¹, is stationary, whilst the outer wall, F², is slowly rotated by worm gear, G, G¹. A series of horizontal perforated platforms, H, are attached to the wall, F¹, and a series of radial fins or scrapers, J, are attached to the wall, F². Hot air or gas is introduced through the pipe, K, and is transferred by centrifugal force into the annular chamber, F, to dry the solid material. The material is then broken up and forced through the perforated platforms in succession by the rotating scrapers, J, and the dried material is finally discharged through the apertures, E¹. In a modification the platforms, H, are alternately inclined in opposite directions and attached to both walls, F¹ and F². Scrapers are also attached to both walls, and are made with inclined edges to fit the spaces between the platforms.—W. F. F.

Separator; Centrifugal —. Automatic control for centrifugal separators. G. M. Bacon, Salt Lake City, Utah. U.S. Pats. 1,321,353 and 1,321,351, 11.11.19. Appl., 19.2 and 6.1.17.

THE rotary separating drum is provided with valves in its periphery to control the discharge of material. The valves are operated by means within the drum which are adapted to be more or less retarded in movement by the density of the material in the drum.—W. F. F.

Centrifugal concentrator. C. Schifferle, Marysville, Cal. U.S. Pat. 1,322,139, 18.11.19. Appl., 14.3.18.

THE basket of a centrifugal machine is divided into three annular compartments, the material under treatment being fed to the middle and largest one, the dressed products overflowing at the top and bottom edges. Liquid is supplied to the innermost compartment (which may be the hollow shaft), and passes through passages in the bottom of the basket to the outermost compartment. The outermost compartment communicates by means of numerous passages with the layer of material under treatment, so that liquid can be supplied to the material without there being any considerable relative circumferential motion between the two. The passages are formed in the shape of elbows, so that as long as there is an inward current of liquid none of the material under treatment will pass outwards.—B. M. V.

Gases; Process of using liquefied — for driving Motors etc. A. Willhelmi, Berlin. Ger. Pat. 312,879, 15.8.16.

CARTRIDGES containing absorbent material are saturated with liquefied gas and placed in closed pressure-containers. By the evaporation of the liquid a regulated supply of gas is rendered available for driving motors etc., or for chemical, metallurgical, or pyrotechnical purposes.—C. A. M.

Gaseous mixtures used in the liquefaction and separation of gases; Process of preventing the contamination of — with lubricants. R. Mewes, Berlin. Ger. Pat. 313,800, 6.2.14.

THE gaseous mixtures used in the liquefaction and separation of gases are liable to become contaminated with lubricants derived from the compressors, expansion vessels, and vacuum pumps of the machine. This is prevented by using a solid lubricant such as paraffin wax, stearine, glue, etc., in admixture with fine graphite.—C. A. M.

Absorbed gases; Separation of — from water. C. Hülsmeier, Düsseldorf-Gratenburg. Ger. Pat. 313,612, 4.8.17. Addition to Ger. Pat. 288,158 of 1913 (this J., 1916, 435).

THE waste from the manufacture of wired (reinforced) glass is ground in order to recover the

glass, the iron wire being removed by magnetic separators. The wire is fine and has a rough surface, and is a very efficient material for liberating absorbed gases from water. It is usually contaminated with powdered glass, but this is not a disadvantage.—W. P.

Boots for use by furnacemen, molten metal workers, and the like; Construction of —. H. E. Gammon, Swansea. Eng. Pat. 134,742, 18.3.19. (Appl. 6736/19.)

THE ordinary fixed vamp of the boot is protected by a detachable vamp, with a ventilating space between the two. A fireproof sole is fixed to the clump sole by hob-nails.

Separating liquids from vapours [in evaporators and stills]; Devices for —. N. A. Holmer, New York. Eng. Pat. 125,939, 28.2.19. (Appl. 5044/19.) Int. Conv., 25.4.18.

IIA.—FUEL; GAS; MINERAL OILS AND WAXES.

Water-gas. J. S. Mc Nicol, Scottish Junior Gas Assoc., Nov. 22, 1919. Gas J., 1919, 148, 493—495.

A YEAR'S work is described with an installation of three complete sets of Humphreys and Glasgow's carburetted water-gas plant at the Temple works of the Glasgow Corporation. The plant is capable of producing 3 million cub. ft. of purified 16-candle power gas per day, using about $2\frac{3}{4}$ galls. of oil per 1000 cub. ft. Trouble was experienced owing to the clinker accumulating on the generator walls gradually diminishing the day's make. Its formation was reduced by using a short cycle of 5 mins., $1\frac{1}{2}$ min. blow and $3\frac{1}{2}$ min. run, with blast at $17\frac{1}{2}$ in. and steam at 28 lb. It was found most economical to shut off a generator after the make dropped to 700,000 cub. ft., and to cut out the clinker by hand. The trouble was probably due to the high ash content of the coke. The average composition of the gas was: CO, 40.2%; H₂, 46.2%; CH₄, 2.1%; CO₂, 4.5%; N₂, 7%. The calorific value was about 300 B.Th.U. gross. The yield of gas was 44,800 cub. ft. per ton of coke, the steam used being about 30 lb. per 1000 cub. ft.—W. P.

Inerts; Effect of — upon the thermal efficiency in the use of gas. J. W. Wood, Midland Junior Gas Assoc., Dec. 4, 1919. Gas World, 1919, 71, 451—453, 476—477.

THE thermal efficiency of a gas must be referred to some particular operation and to some particular form of appliance or burner, though the best results are not obtained with the same appliance with all gases. A gas with a lower maximum efficiency may prove more useful in practice if it has a greater

working range over which this efficiency is maintained. The addition of "inerts" results in an increase in specific gravity of the gas, and a greater volume of gas must be passed to obtain the same heat value. At the same time less air is required for complete combustion, and aeration is improved. The decrease in flame temperature is small in comparison with the volume of inert gas added, on account of the large percentage of nitrogen already present in the air in which the gas has to burn, and the small change in volume of the gas-air mixture for complete combustion (this J., 1919, 707 A). Provided the border line between permissible practice and prohibitive qualities is not reached, for all practical purposes carbon dioxide may be treated as nitrogen. It is possible to add 25% of "inerts" to coal gas without depreciating the performance of the gas so badly as to make it commercially impracticable. The addition of air to coal gas is similar in effect to the addition of nitrogen, but in case of inefficient mixing local irregularities may occur in the gas mixture, parts of which may reach the explosion danger limit.—W. P.

Motor benzol; Production of — in medium and small gasworks. Steding. J. Gasbeleucht., 1919, 62, 635—636.

THE author advises the installation of benzol-washing processes in small gasworks. The calorific value of the gas is thereby reduced (about 6% for the removal of 30 grms. of benzol per cub. m. of gas), but the deposition of carbon by the burning gas is diminished. The costs of plant, materials, etc., are examined, together with the prices obtainable for the products, the clear profit on a year's working being greater than the cost of plant. A yield of 60,000 kilos. of benzol is estimated per year's production of 3 million cub. m. gas (20 grms. per cub. m.).—W. P.

Acetylene, ethylene, and benzene; Gas-analytical separation of —. W. D. Treadwell and F. A. Tauber., Helv. Chim. Acta, 1919, 2, 601—607.

THE quantitative absorption of acetylene from mixtures containing it, together with ethylene and benzene vapour, is conveniently effected with a solution of mercuric cyanide (20 grms.) in 2N sodium hydroxide solution (100 c.c.); the gas is shaken with the mixture (5 c.c.) for 1-2 minutes, at the end of which the acetylene is completely absorbed, whilst ethylene and benzene vapour are unaffected. A solution of mercuric nitrate (20 grms.) in 2N nitric acid (100 c.c.) which has been saturated with sodium nitrate is recommended for the absorption of ethylene in the presence of benzene vapour; the gas is agitated with 5-10 c.c. of the solution for 2-3 minutes. Propylene appears to behave similarly to ethylene, since it is indifferent to alkaline mercuric cyanide solution whilst readily absorbed by mercuric nitrate solution.—H. W.

Petroleum; Genesis of — as revealed by its nitrogen constituents. C. F. Mabery. J. Amer. Chem. Soc., 1919, 41, 1690—1697.

It has already been shown that the heavier varieties of petroleum from the California, Texas, Ohio, Canadian, Russian, and similar fields are complex mixtures of the denser hydrocarbons with oxygen, sulphur, and nitrogen derivatives; they all differ widely in composition from the lighter varieties in the eastern territory of the United States. An examination of twenty-one specimens of the latter, however, discloses in every case the presence of nitrogen in amount ranging from 0.01 to 0.48%, so that the conclusion is justified that nitrogen is contained in the petroleum of all the principal oilfields in form of combination which could have had their origin only in the remains of vegetable or animal bodies. Presumptive evidence has been given that

the associated hydrocarbons in petroleum had the same origin. The nitrogen was estimated by Kjeldahl's process on the one hand, and by a process which is a combination of the Dumas procedure for nitrogen and the oxygen combustion for carbon on the other hand. The results given by the two methods show very fair agreement. (See also J. Chem. Soc., Jan., 1920.)—H. W.

Viscosity of hydrocarbon oil mixtures; Method for calculating —. W. F. Espy. Petroleum (Chicago), 1919, 8, 27–28.

VISCOSITY numbers are not additive, and therefore no factor can be applied to the calculation of the viscosity of a mixture which will take into account the mutual effect on viscosity of each component. The author constructs an empirically-derived chart, made up of the observed viscosities of mixtures of a light and heavy oil respectively and plotted in terms of a percentage mixture of oils of higher and lower viscosities. These percentages are additive, and from such a chart there may be read off directly the volume of the two components which will give a resulting mixture of the desired viscosity.

—A. E. D.

Paraffin; Thermal expansion of and solutions of —. W. von Piotrowski. Z. physik. Chim., 1919, 93, 596–606.

THE coefficient of expansion of solid paraffin from petroleum lies between 0.000812 and 0.005108. Lignite tar paraffin has about the same value, but when molten the value is about double. The dependence of the specific gravity on the temperature in the case of solutions of paraffin in solvents of high specific gravity may be expressed by the mixture rule, but in the case of solvents of low specific gravity irregularities are found in the region of the melting point. The specific gravity of solutions, at temperatures above the melting point of the paraffin, may be approximately calculated by the mixture rule. (See also J. Chem. Soc., 1920, i., 1.)

—J. F. S.

PATENTS.

Peat fuel; Manufacture of — from damp peat as dug from the bog strata. S. C. Davidson, Belfast. Eng. Pat. 131,326, 31.10.18. (Appl. 17,483/18.)

RAW peat as dug from the bog is thoroughly mixed with slaked lime until the mixture attains a homogeneous putty-like consistence. The water is then expelled by subjecting the mixture to mechanical pressure. Briquettes formed in this manner are claimed to be free burning, and to constitute a suitable fuel for household and industrial purposes.

—W. P.

Briquettes from (a) flue dust or (b) sawdust and the products resulting therefrom; Manufacture of —. C. Michel and V. Raskin, Paris. Eng. Pats. (a) 131,886 and (b) 131,887, 2.11.18. (Appls. 17,945 and 17,946/18.)

A MIXTURE is first prepared containing (a) flue dust or culm or (b) sawdust and coal dust with pitch and a mineral addition consisting of lime and/or cement and/or a little dry clay. The pulverised ingredients are mixed whilst cold and then introduced into a closed agitator where the temperature is raised to 150°–180° C. The pitch softens, moisture is given off from the wood, and the cement and lime commence to set. The paste is compressed under a pressure of 200–300 kilos. per sq. cm. and allowed to cool in moulds, forming a compact block.—W. P.

Washing coal or other minerals or materials. C. Burnett, Trowbridge. Eng. Pat. 131,596. (Appls. 17,873, 1.11.18, and 19,112, 26.11.18.)

THE apparatus is particularly applicable to the washing of slack or fine coal. The coal is fed on to an endless belt, on to which play jets of water, which carry the coal along in the opposite direction to which the belt is travelling. The coal is delivered into a second washing chamber in which water is forced through the coal by an intermittent or pulsating process. The belt inclines downwards into the second tank. The water from the second washing is conveyed to a settling tank, from which the slurry is again conveyed for treatment to the second washing tank.—W. P.

Coke; Apparatus for quenching —. S. N. Wellington, London. Eng. Pat. 131,867, 19.8.18. (Appl. 13,452/18.)

A RECEPTACLE, adapted to run on rails, receives the whole charge of coke from the oven upon a conveyor at the bottom of the receptacle, which is provided with a water jacket from which hot water may be supplied under the pressure of the steam in the water jacket for quenching the charge.

—W. P.

Coke ovens; Heating walls of — and blocks for the construction of such walls. A. Roberts, Chicago, U.S.A. Eng. Pat. 135,091, 7.3.19. (Appl. 5718/19.)

THE walls are so designed that the desired proportion of heat from the heating gases will travel towards the interior of the carbonising chamber, leaving only a portion of the heat for the recuperating structure. Blocks in the heating wall are recessed to provide a number of gas passages in the body of the wall, so that a greater amount of heat is delivered into one face of the wall than into the opposite face. Blocks particularly adapted for the construction of such a heating wall are described.

—W. P.

Coke [from pitch]; Manufacture of —. J. Becker, Assignor to Koppers Co., Pittsburgh, Pa. U.S. Pat. 1,320,371, 4.11.19. Appl., 15.3.18.

A COKE-PITCH mixture is coked, the residue is again coked after addition of more pitch, and the process is repeated until a substantially ash-free coke is obtained, derived in the main from pitch.—A. E. D.

Coke-oven iron work. L. Wilputte, Assignor to A. A. Wilputte, New Rochelle, N.Y. U.S. Pat. 1,320,432, 4.11.19. Appl., 27.5.18.

AT the opposite ends of horizontal coke ovens are placed flash plates and metal connecting members. The oven masonry is recessed to hold these metal parts.—W. P.

Chamber oven. H. Bröcker, Harburg. Ger. Pat. 314,118, 30.11.17.

PRODUCERS are built between the gasifying chambers. The upper layers of coke in the producers are heated by the hot gases from the neighbouring chamber. Any chamber can be cut out when necessary for repairs without the working of the rest being discontinued.—W. P.

Safety device against explosions for gas mains [of coke ovens]. R. Wilhelm, Altenessen. Ger. Pat. 313,649, 8.3.16. Addition to Ger. Pat. 308,073.

A MEMBRANE attached to a gas main operates two valves passing water into a water seal and indifferent gas respectively when the pressure diminishes, so that the current of inert gas can only pass in one direction, i.e., through that portion of the gas main beyond the membrane.—D. W.

Water-gas producers. Comp. pour la Fabrication des Compteurs et Matériel d'Usines à Gaz. Paris. Eng. Pat. 112,268, 17.12.17. (Appl. 18,757/17.) Int. Conv., 19.12.16.

THE producer is fitted with a false grate to support the coke and effect the sharp separation of the clinker without withdrawing the coke. The producer grate is rectangular in shape.—W. P.

Water-gas plants; Operation of —. H. E. Smith, London. Eng. Pat. 134,573, 3.8.18. (Appl. 12,694/18.)

AN improved arrangement of the valves and gearing for operating water-gas plants of the twin generator type (Eng. Pat. 24,893 of 1908; this J., 1909, 876) is described, gas making being intermittent, and the direction of travel of the steam during the gas-making period being reversed after each of the blowing periods. Dry-faced centre valves for the direction of the air and blow gases are coupled to work in conjunction with the steam inlet connection and gas outlet by operating one central shaft. The pressure of the blowing plant may be utilised for the operation, using a floating bell suitably connected to rotate the centre valves. The bell is released at certain intervals of time according to the adjustment of the air-regulating valves.—W. P.

Hydrogen or water-gas; Apparatus for the production of — from exhaust steam. F. Lang, Frankenthal. Ger. Pat. 313,917, 24.9.16.

IN apparatus for the production of hydrogen or water-gas from exhaust steam, an attachment to the producer automatically releases the back-pressure of the steam during the periods in which the steam is not led into the producer. The steam is superheated before entering the producer, either by the waste heat of the producer or of the gases generated, or, if the supply of exhaust steam is insufficient, by the addition of highly-superheated steam from other sources. In the latter case sufficient superheated steam to maintain the required pressure is automatically led into the exhaust steam supply by means of a reducing valve.

—L. A. C.

Producer-gas; Generation of —. H. W. Bamber and E. Goldschmid-Abrahams, London. Eng. Pat. 134,113, 23.12.18. (Appl. 21,539/18.)

MEANS are described for automatically controlling the water supply to a gas producer with change of temperature, making use of the expansion and contraction of the fire-box of the producer or of some part in contact with the latter. The temperature of the furnace may be recorded by means of an indicator in connection with the device, which is intended primarily for use in producers for automobile vehicles.—W. P.

Gas from solid fuel for automobile internal combustion engines and the like; Construction of generators for —. J. W. Parker, Harrow, Middlesex, and E. Goldschmid-Abrahams, London. Eng. Pat. 134,300, 29.10.18. (Appl. 17,647/18.)

THE producer consists of an inner casing made up of superimposed sections of cast iron enclosed by an outer sheet-metal shell, forming an annular space round the furnace through which passes the air for combustion. The lower sections are provided with radiating fins which divide the annular space into vertical conduits.—W. P.

Combustible gas; Apparatus for producing —. W. Pickard, Rochdale, and D. R. Dobson, Bolton. Eng. Pat. 134,907, 11.11.18. (Appl. 18,430/18.)

COMBUSTIBLE gas is prepared from liquid hydro-

carbon by passing the vapours mixed with steam through a red-hot mass of charcoal and iron filings (Eng. Pat. 122,079; this J., 1919, 128A). In an improved form of apparatus a burner is placed at the bottom of a central aperture, in which is situated a casing, which is in communication with chambers, the first containing iron filings and the second a mixture of charcoal and iron filings.

—W. P.

Gas generators. E. Svensson and M. A. Crank, Copenhagen. Eng. Pat. 134,454, 11.2.19. (Appl. 3358/19.)

THE producer is downward burning and is intended for low-grade fuels. Horizontally above the main

fire, resting on the grate, 3, are arranged one or more cavities in a circle, the number and size of these cavities being so chosen that they maintain a circular layer of burning fuel filling the whole circumference of the producer. These cavities contain stepped grates, 7, for supporting the fuel. When the producer is working, air from the interior of the producer, and also steam if the fuel used is moist, pass through the pipes, 8, and the grates, 7, into the burning fuel.—W. P.

Gas producers; Apparatus for the automatic cleaning or clinkering of —. J. Moussiaux, Huy, Belgium. Eng. Pat. 135,058, 1.2.19. (Appl. 2526/19.)

IN water-sealed producers the layer of combustible is supported by a somewhat thick layer of clinker, which itself rests on a revolving bed provided with chimneys or shoots for the discharge of the clinker into an external circular channel. The bottom of each chimney is formed of a fixed circular track above which the chimney travels. In each chimney the lower part of the back wall is cut away in such a manner that the clinker can spread over the track on the rotation of the chimneys, being afterwards removed by suitable scrapers or rakes formed by the front wall of the following chimney.—W. P.

Coal- and water-gas; Apparatus for the manufacture of combined —. W. D. Wilcox, Chicago, Ill. U.S. Pat. 1,321,963, 18.11.19. Appl., 17.1.16.

WASTE gases from a producer chamber pass upwards around a vertical gas retort, then into a flue containing a steam superheater. The retort is provided with a number of gas outlets at different levels through which the gases given off at different temperatures may be withdrawn separately and continuously.—W. P.

Peat and the like; Manufacture of ammonia and combustible gas or coke from —. F. Sauer, Potsdam. Ger. Pat. 314,015, 18.2.13.

DRIED peat or the like is heated in a shaft furnace so arranged that decomposition is effected in three separate zones. A mixture of air and steam is led in both at the top and bottom of the upper zone, which contains the fresh peat, and the ammonia generated is led away from the middle of the zone; the material passes slowly down through the middle neutral zone into the lower zone, and the combustible gas produced in the lower zone is led away through a separate outlet. The pressure of the mixture of air and steam led into the upper zone is regulated by the pressure of gas escaping from the lower zone.—L. A. C.

Ammonia and tar recovery process [for producer-gas]. J. van Ackeren, Assignor to Koppers Co., Pittsburgh, Pa. U.S. Pat. 1,320,369, 4.11.19. Appl., 26.5.19.

PRODUCER-GAS, superheated with respect to its tar vapour and water content, is freed from dust by electrical precipitation, and is then cooled to a point at which tar vapours are condensed whilst the water is still in the state of vapour. The tar mist is then electrically precipitated.—A. E. D.

Gas washer. Simon-Carves, Ltd., and J. H. Brown, Manchester. Eng. Pat. 133,987, 19.9.18. (Appl. 15,208/18.)

THE gas is made to pass in a horizontal direction alternately through spaces having positive means for production of spray, and through latticed slats kept wet by the spray. A spray catcher consisting of vertical and horizontal baffles is placed before the outlet of the washer.—W. P.

Gas washer. A. A. Goubert, Englewood, N.J., Assignor to H. Bentz, Montclair, N.J. U.S. Pat. 1,320,852, 4.11.19. Appl., 1.5.18.

A GAS washer is provided with a number of baffles consisting of closely arranged plates over which water is kept flowing. The plates in successive baffles increase in number, and decrease in cross-sectional area, and also in respect to the horizontal and vertical spaces separating them.—W. P.

Gas liquor; Process for removing acid constituents from —. Gewerkschaft des Steinkohlenbergwerks Lothringen, Gerthe. Ger. Pat. 313,918, 16.7.18.

IN A continuous process for removing the acid constituents from gas liquor by distillation, the gases produced are freed from ammonia by washing, the solution being returned to the still. The residual gases pass through a second wash column, which is arranged in two sections, to effect the separation of water rich in hydrogen sulphide from the upper portion, and water rich in carbon dioxide from the lower portion.—W. P.

Hydrocarbon; Rectification of —. De Bataafsche Petroleum-Maatschappij, and J. H. C. de Brey, The Hague. Eng. Pat. 123,522, 30.10.18. (Appl. 17,741/18.) Int. Conv., 21.2.18.

TO separate a mixture of two volatile components, e.g., natural gas containing gasoline, and recover the gasoline, a process of rectification under pressure is claimed. A preliminary treatment consists in applying sufficient pressure to form a two-phase system, which is then submitted to rectification. A pressure of 20 atmospheres or more may be employed.—A. E. D.

Peat, waxes, oils, or fats; Production of — from peat, peat-straw, mosses, lichens, algae, grass, straw, pine needles, and the like. K. H. V. von Porat, Stockholm. Eng. Pat. 133,989, 21.9.18. (Appl. 15,357/18.)

THE vegetable matter is extracted by means of terpenes or their derivatives, having a boiling point higher than 100° C. (e.g., oil of turpentine), preferably under pressure.—A. E. D.

Oil-converting apparatus. J. H. Adams, Brooklyn, N.Y., Assignor to Texas Co., Houston, Tex. U.S. Pat. 1,320,351, 28.10.19. Appl., 1.12.09.

OIL is supplied continuously, under pressure, to an elongated retort of restricted cross-section, to which a high temperature is applied locally. The vapours are maintained in contact with the oil surface during the cracking operation, and are subsequently condensed.—A. E. D.

Oils; Process and apparatus for the conversion of liquids, fluids, and —. J. H. Adams, Brooklyn, N.Y., Assignor to Texas Co., Houston, Tex. U.S. Pat., (a) 1,320,726 and (b) 1,320,727, 4.11.19. Appl., 31.12.14 and 29.3.15.

(A) HIGH-boiling oil is subjected to heat under its own vapour pressure. Superheated steam is introduced into the oil and the volatile products are separated from the heavy residues, which are re-treated. (b) In an apparatus for carrying out the process described under (a), automatic pressure-control valves are provided between the still and the condenser and also at the end of the condensing worm. A thin horizontal cracking still containing a metal of melting point lower than the cracking point of the oil may be used. It communicates with an expansion dome, from which the converted vapours may be withdrawn at the top and the unconverted oil at the bottom.—A. E. D.

Hydrocarbon oils; Treatment of —. R. H. Brownlee, Pittsburgh, Pa. U.S. Pat. 1,320,376, 4.11.19. Appl., 11.7.17.

A CURRENT of gas is introduced near the lower end of a treating system, which is heated and maintained under pressure, and oil is introduced at a point below the upper end of the system. The oil and vapour flow upwards through the system, passing at intervals through areas in which the speed is reduced in order to cause separation of the heavier components. The separated heavy oils flow downwards in counter current to the stream of gas. Part of the separated heavy oil is trapped in the zones where the speed is reduced, and the trapped oil is from time to time drawn off into the lower part of the apparatus.—A. E. D.

Petroleum products; Apparatus for treating —. U. S. Jenkins, Chicago, Ill. U.S. Pat. 1,321,749, 11.11.19. Appl., 27.9.16.

FOR the production of light oils, heavy hydrocarbons are treated under pressure in a still fitted with means for removing vapours of "greater average density than that of the lowest produced in the still from selective points below the top of the still," and for mechanically circulating the liquid in the still.—L. A. C.

Briquette machine. F. H. Rogers, London. From St. Louis Briquette Machine Co., St. Louis, Mo., U.S.A. Eng. Pat. 135,061, 5.2.19. (Appl. 2839/19.)

Gas generators or the like; Apparatus for feeding fuel to —. G. H. Bentley and E. G. Appleby, London. Eng. Pat. 135,272, 18.11.18. (Appl. 18,888/18.)

Coal and the like; Method of cleaning —. H. R. Conklin, Joplin, Mo., U.S.A. Eng. Pat. 130,972, 7.7.19. (Appl. 16,976/19.) Int. Conv., 5.8.18.

SEE U.S. Pat. 1,290,516 of 1919; this J., 1919, 166 A.

Petroleum and the like; Method and apparatus for distilling —. E. C. R. Marks, London. From Cleveland Trust Co., Cleveland, Ohio, U.S.A. Eng. Pat. 134,567, 21.4.18. (Appl. 6921/18.)

SEE U.S. Pat. 1,260,584 of 1918; this J., 1918, 293 A.

Fuel; Liquid —. E. C. R. Marks, London. From United States Industrial Alcohol Co., New York. Eng. Pat. 131,766, 30.1.19. (Appl. 10,712/19.)

SEE U.S. Pat. 1,296,902 of 1919; this J., 1919, 353 A.

IIb.—DESTRUCTIVE DISTILLATION; HEATING; LIGHTING.

PATENTS.

Petroleum pitch; Destructive distillation of —. K. Nomi, Kitatoshimagnn, Japan. Eng. Pat. 114,617, 11.2.18. (Appl. 2432/18.) Int. Conv., 4.4.17.

PETROLEUM pitch is distilled at about 500°—600° C., oil and gas being produced, and a pure coke left. The gas is mainly hydrogen.—A. E. D.

Destructive distillation of carbonaceous materials. F. M. Perkin, and Nitrogen Products and Carbide Co., Ltd., London. Eng. Pat. 134,236, 19.2.18. (Appl. 2920/18.)

INCLINED or vertical retorts of refractory material for low temperature distillation of coal etc. are provided with passages or channels in the walls for the preliminary passage of superheated inert gas or steam, in order to increase the yield of tar, tar oils, and paraffin hydrocarbons. The retorts are elliptical in cross-section, and are connected together in pairs.—W. P.

Carbons for electric arc lamps. W. Heape, London, and H. B. Grylls, Weybridge. Eng. Pat. 133,376, 2.8.18. (Appl. 12,662/18.)

THE carbons are enclosed whilst dry in a chamber or receptacle which is then evacuated. The chamber or carbons may be heated during the evacuation. After thus removing occluded gases, the carbons are immersed in an impregnating liquid. (See Eng. Pats. 126,673 and 128,057; this J., 1919, 455 A. 568 A.)—B. N.

Mercury arc lamp. P. G. Nutting, Wilksburg, Pa., Assignor to Westinghouse Electric and Manufacturing Co. U.S. Pat. 1,320,087, 28.10.19. Appl., 13.3.18.

A MERCURY arc lamp comprises anode and cathode legs, and a connecting arc tube formed of hard glass softening only at a high temperature. Tungsten leading-in wires and terminals are sealed into the ends of the legs.—B. N.

Incandescence cathode for discharge tubes. W. Germershausen, Leipzig. Ger. Pat. 303,274, 16.3.17.

THE cathode is composed of a resistant material of high melting point, e.g., iridium, upon which a thin layer of a metal such as tungsten, affording copious emission of electrons when heated, is wound spirally, in direct electrical contact.

—J. S. G. T.

Distillation of waste liquors. Eng. Pat. 120,721. See V.

Distillation of waste cellulose lyes. Ger. Pat. 313,607. See V.

III.—TAR AND TAR PRODUCTS.

Naphthalene; Manufacture of pure — from coal tar. J. A. Davy. Coke Oven Managers' Assoc., Nov. 29, 1919. Gas J., 1919, 148, 489—490.

THE naphthalene is present in the carbelic and light creosote oils, which represent about 20—25% of the tar distilled. These oils are washed for carbelic and cresylic acids before further treatment, as the latter have the effect of keeping the naphthalene in suspension. After cooling for a period of 48 hours the excess oil is drained off from the precipitated naphthalene, which is then distilled in a 10-ton gas-fired still. Large flaky crystals are obtained which still contain 25—30% of oil. The main quantity of this is removed by hydraulic pressure (35 cwt. to 2 tons per sq. in.) in a steam-jacketed press. The "pressed naphthalene," containing about 1% of oil, is then melted and washed, first with sulphuric acid and then with caustic soda solution, these being followed by sodium sulphate solution, on which the naphthalene floats. After separation it is subjected to a final distillation. The yield of finished product from crude "salts" is 40—45%.—W. P.

Side-chain oxidations with potassium permanganate. [Oxidation of nitrotoluenes to nitrobenzoic acids.] L. A. Bigelow. J. Amer. Chem. Soc., 1919, 41, 1559—1581.

THE action of potassium permanganate in alkaline solution on the three nitrotoluenes has been investigated with a view to determining the optimum conditions for the technical preparation of the nitrobenzoic acids. The experiments were usually performed by gradually adding the solid permanganate to a boiling suspension of the nitrotoluene in aqueous sodium hydroxide solution. Changes in the conditions of oxidation, in general, merely cause a different proportion of the nitrotoluene to be attacked by the oxidising agent, the ratio of nitrobenzoic acid produced to unchanged nitrotoluene remaining essentially constant. It is concluded, therefore, that the quantity of nitrotoluene or nitrobenzoic acid entirely destroyed by the oxidising agent is practically constant and almost independent of the oxidation procedure, and that at least two entirely independent actions take place, namely, the oxidation of the organic compound and the decomposition of the permanganate into manganese oxides and free oxygen. Increase in the concentration of the alkali in the oxidising mixture up to a certain point favours the oxidation of *o*-nitrotoluene, beyond which point a further increase produces essentially no effect, all other conditions being kept constant. By this increase in alkali concentration the oxidation of the *meta*-isomeride is hindered, such oxidation being most effective in an essentially neutral medium; with *p*-nitrotoluene, oxidation is favoured up to a certain point, beyond which the quality of the product becomes very poor. Increasing dilution of the reaction mixture favours the oxidation of all the nitrotoluenes, probably owing to retardation of the decomposition of the permanganate into manganese oxides and oxygen. Under all circumstances *p*-nitrotoluene is oxidised most readily, the *ortho*-compound next, and the *meta*-isomeride least readily. Nearly the same results are obtained when the oxidation is effected in copper or enamel-lined vessels, but distinctly lower yields and products of poorer quality result when iron vessels are used both with and without alkali. The addition of salts of calcium and magnesium produces no noticeable effect in the oxidation of *p*-nitrotoluene in neutral solution, and a like result is obtained when pyridine is added to an alkaline solution, although the latter acts as a powerful negative catalyst in certain permanganate reactions. (See also J. Chem. Soc., 1920, i., 20.)—H. W.

Motor benzol. Steding. See IX.

Tetralin. Vollmann. See XIII.

PATENTS.

Carbazole; Production of high percentage —. Soc. d'Eclairage, Chauffage, et Force Motrice, Paris. Eng. Pat. 121,455, 7.10.18. (Appl. 16,291 18.) Int. Conv., 4.12.17.

CRUDE carbazole is dissolved in phenols, such as commercial carbolic acid, cresols, or xylenols at about 70° C., using 5–10 parts of solvent according to the richness of the carbazole; the solution is filtered hot, and the crystals which separate on cooling are washed with a small amount of the cresol mixture. The product from the first crystallisation yields an 80% carbazole, which may be purified to 90% by a second crystallisation from phenol or its homologues. The crude carbazole used as the initial material may consist of the residue obtained by distilling the liquor from the purification of anthracene by means of pyridine. Crude carbazole may also be obtained by the action of water on potassium-carbazole, produced by treating crude or concentrated anthracene with caustic potash.

—J. F. B.

Benzyl chloride and benzal chloride; Production of — and of certain homologues and substitution products of these compounds. Levinstein, Ltd., H. Levinstein, and W. Bader, Manchester. Eng. Pat. 131,250, 27.7.18. (Appl. 12,227/18.)

PRODUCTS chloro-substituted in the side chain are obtained by treating hydrocarbons at temperatures below 0° C. with hypochlorous acid in aqueous solution. Thus, for example, toluene (3 mols.) is emulsified with a hypochlorite solution containing 1 mol. of active chlorine, the mixture is cooled to –5° C., and dilute sulphuric or other acid ($\frac{1}{2}$ mol.) is added gradually. The product contains unchanged toluene, 60–70% of the theoretical quantity of benzyl chloride, and small quantities of benzal chloride and other chlorinated products, and is purified by fractional distillation. Similarly a second atom of chlorine can be introduced, it preferably occupying a position in the methyl group already substituted if more than one side chain is present. The method is not applicable to nitro-substitution products, sulpho-chlorides, or cresol esters, whilst sulphonic acids under these conditions are substituted in the nucleus.

—G. F. M.

Quinone; Preparation of —. J. M. Weiss, New York, and C. R. Downs, Cliffside, N.J., Assignors to The Barrett Co. U.S. Pat. 1,318,631, 14.10.19. Appl., 27.5.18.

BENZOQUINONE is produced by subjecting benzene in the vapour phase to the action of a gas containing oxygen at a suitable temperature and in the presence of a suitable catalyst.—G. F. M.

Benzene; Catalytic oxidation of —. J. M. Weiss, New York, and C. R. Downs, Cliffside, N.J., Assignors to The Barrett Co. U.S. Pat. 1,318,633, 14.10.19. Appl., 8.4.19.

BENZENE is oxidised to compounds containing hydrogen, oxygen, and less than six carbon atoms by the action of a gas containing oxygen at a temperature of 300°–500° C. in the presence of a suitable catalyst.—G. F. M.

Phenols and their substitution products; Preparation of aromatic —. E. H. Zollinger and H. Roehling, Berlin. U.S. Pat. 1,321,271, 11.11.19. Appl., 16.11.15.

AN aromatic halogen compound, in which the halogen can be substituted by hydroxyl, is heated

under pressure to the temperature of saponification with a solution of an alkali hydroxide and a lead salt which forms an insoluble compound with the phenol. The reaction mixture is then quickly cooled to cause the crystallisation of the metallic compound of the phenol, and this is separated and decomposed to liberate the free phenol.—G. F. M.

Benzaldehyde; Production of —. J. M. Weiss, New York, N.Y., and C. R. Downs, Cliffside, N.J., Assignors to The Barrett Co. U.S. Pat. 1,321,959, 18.11.19. Appl., 25.6.19.

BENZALDEHYDE is produced by passing a mixture of toluol vapour and a gas containing oxygen over an oxide of molybdenum heated above 500° C.

—L. A. C.

Anthranilic acid; Process of producing —. R. S. Potter, Grantwood, N.J., Assignor to The Barrett Co. U.S. Pat. 1,322,052, 18.11.19. Appl., 17.6.19.

As a step in the manufacture of anthranilic acid, carbon dioxide is passed into a solution containing an alkali anthranilate and an alkali carbonate to convert the carbonate to the bicarbonate; the precipitated bicarbonate is separated by filtration, and an excess of sulphur dioxide is passed into the filtered liquor.—L. A. C.

Isonitrosoacetanilide and its substitution products; Production of —. J. R. Geigy A.-G., Basle. Ger. Pat. 313,725, 11.5.18.

CHLORAL hydrate in presence of hydroxylamine or hydroxylamine sulphonic acids is allowed to act at an appropriate temperature on aniline or its ring-substituted halogen, alkyl, alkyloxy, or carboxyl derivatives, or their N-monoalkyl or monoaryl derivatives. Chloraloxime is formed and reacts further thus:—

Hydroxylaminesulphonic acid is prepared by slowly adding 50% sulphuric acid to a mixture of sodium nitrite solution, ice, and bisulphite until the liquid turns Congo red paper distinctly blue. The separation of the sodium hydroxylaminedisulphonate first formed into hydroxylaminesulphonic acid and sodium sulphate proceeds rapidly but is only completed after standing for two days. On boiling under a reflux condenser, hydroxylamine sulphate is produced, and this gives, when boiled with aniline and chloral hydrate, isonitrosoacetanilide, bright yellowish plates, m. pt. 175° C. with decomposition, slightly soluble in cold water, benzene, fairly soluble in ether and alcohol, precipitated from solutions in dilute alkalis by acids. On warming with strong sulphuric acid it yields isatin- β -imine, which separates into isatin and ammonium sulphate when its dark red solution in sulphuric acid is diluted with water. *p*-Chloroaniline gives with hydroxylamine sulphate and chloral hydrate isonitroso-acet-*p*-chloroanilide, white needles, m. pt. 165° C., slightly soluble in cold water and ether, soluble in alcohol.—H. J. H.

Phenolic bodies; Manufacture of sulphonates of aromatic hydrocarbons for use in making —. F. Cohellis, Charleston, W.Va., U.S.A. Eng. Pat. 131,715, 6.2.19. (Appl. 2946/19.)

IV.—COLOURING MATTERS AND DYES.

Indigo industry; Future prospects of the natural —. Effect of superphosphate manuring on the yield and quality of the indigo plant. W. A. Davis. Agric. Res. Inst., Pusa. Indigo Publ. No. 4, 1918. 19 pages.

The changes imposed on indigo cultivation in Bihar by the appearance of synthetic indigo have resulted in the rapid impoverishment of the indigo soils in recent years and a consequent serious reduction in the yield of dye. Superphosphate manuring has now been tried on several estates, and very favourable results have been obtained, confirming the view previously advanced (Indigo Publ. No. 1, this J., 1918, 194 K; 1919, 248 A), that the depletion of available phosphate in the soil was the principal cause of the failure of indigo crops. Not only was the actual yield of green plant per acre far higher in the case of superphosphate-treated land, but the quality, or richness in indican, was superior, so that the yield of eake indigo amounted to as much as 32 seers (64 lb.) per acre for a single cutting, more than was ever obtained from the Java plant in its best days.—G. F. M.

Indigo; Loss of — caused by bad settling and means of obviating this. Use of dhak gum, its effect on yield and quality. W. A. Davis. Agric. Res. Inst., Pusa. Indigo Publ. No. 3, 1918. 16 pages.

The use of dhak gum, a ruby-coloured exudation from the dhak tree (*Butea frondosa*) is recommended to improve the settling of indigo after heating. An increase in yield of 3–6 seers (6–12 lb.) of indigo per 100 maunds (8000 lb.) of plant has been obtained, representing an increase of about 70% with Sumatran plants and 35% with Java plants, and no appreciable deterioration of quality ensues. Dhak gum is most useful in factories where so-called "green vats" are obtained, but even under very favourable conditions of fermentation perfect settling is rare, and use of the gum as part of the ordinary routine is advisable, as even if the seed-water contains only 1 part of indigo in 10,000 it represents a loss of 30% with Sumatran working. The gum should be used in the proportion of 1 seer (2 lb.) to 100 maunds (8000 lb.) of plant, a strained solution being added to the beating-vat about 5 mins. before beating is ended.—G. F. M.

Indican from indigo-yielding plants; Improved method of preparing —. B. M. Amin. Agric. Res. Inst., Pusa. Indigo Publ., No. 5, 1919, 9 pages.

An improved and simplified method of isolating indican, applicable to all *Indigofera* sp. and other indigo-yielding plants, and admitting of the separation as indican hydrate of at least 80% of the glucoside present in the aqueous extract of the leaves, is carried out as follows:—The leaves are twice extracted with boiling water, and the extract is treated with slaked lime and filtered to remove gums, tannins, etc. The filtrate is evaporated in an open dish, treated with carbon dioxide to precipitate the lime still in solution, and after refiltration the clear solution is evaporated to a thick syrup, which is extracted three or four times with acetone. The acetone is distilled off from the extract, and the aqueous residue, when cooled in ice, sets to a crystalline mass of crude indican hydrate, $C_{14}H_{17}O_5N \cdot 3H_2O$. The crystals are separated and dried at the ordinary temperature. Pure white anhydrous indican, m. pt. 177°–178° C., is obtained by precipitation with benzene from a hot alcoholic solution of the hydrate.—G. F. M.

PATENTS.

Quinone dyestuffs; Production of —. M. Becke, Weidling, W. and H. Suida, Vienna. Ger. Pat. 300,707, 12.6.15.

NAPHTHAQUINONES or their derivatives are combined

with aminobenzenesulphonic acids which contain a further free or substituted amino or hydroxyl group or with dyestuffs containing amino or sulphonic groups in the proportion 1 mol. quinone to 1 reactive amino group. The reaction is effected in aqueous solution or suspension or by grinding together the reacting substances. Thus aminoazo dyestuffs are combined with naphthaquinone, so that each molecule of the latter or its derivative reacts with one amino group, by the aid of an oxidising agent, air, or even another molecule of quinone. When the naphthaquinone contains separable negative substituents the combination is effected by such condensation agents as carbonates, bicarbonates, or acetates. Here, also, when a sulphonic group is split off, the addition of an oxidising agent capable of giving up one atom of oxygen is advantageous. While the colour is often completely formed in the cold in aqueous solution or suspension, the application of heat is more usually necessary, especially with nitrosonaphthols. The resulting dyestuffs are soluble in water and contain a quinone nucleus which promotes adhesion to the fibre; the fastness of the shades produced is increased by after-treatment with metallic salts.

Solutions of organic substances. Ger. Pat. 313,726. See XX.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Wool; Absorption and retention of soap by —. A. Woodmansey. J. Soc. Dyers and Col., 1919, 35, 169–171.

CROSS-BRED serge, spun silk yarn, cotton wool, and cotton cambric were found to absorb from a 1% solution of Castile soap 3.6, 1.8, 1.4, and 0.4% respectively of fatty acid calculated on the weight of material treated. The author describes a number of experiments which indicate that preferential absorption of the basic component of the soap occurs and show that, within limits, absorption increases with the duration of immersion and the concentration of the soap bath, and that the amount of soap remaining in cloth on scouring depends on the nature and thoroughness of the scouring process.

—S. S. A.

Wool and silk; Colouring of — with strong acids. P. Waentig. Text. Forsch., 1919, 1, 59–63. Chem. Zentr., 1919, 90, IV., 492.

If boiling 50% sulphuric acid or fuming hydrochloric acid is poured on to wool in presence of a few crystals of sugar, a red colour develops in a short time. Without the sugar pure wool gives very little colour, at most only a faint rose tint, but in presence of considerable quantities of cotton, or artificial silk, or of other cellulosic substances or of substances, such as pentosan, yielding furfural, a decided red colour is produced. The presence of fat in the wool leads to a brown colour. Silk behaves in a similar manner to wool.—B. V. S.

Cotton fibres and yarns; Effect of certain industrial processes on the strength of —. R. S. Greenwood. J. Textile Inst., 1919, 10, 274–278.

THE material used for the investigation was a sample of Sakelarides' Egyptian cotton; its grade was estimated as "fully good, fine staple," and the average length was 1½ in. to 1¾ in. The results appear to show that a yarn realises more of the available strength of the individual fibres than has been previously assumed. Previous observers give 20–25% as the strength realised, as compared with 67% found by the author. By mereerising yarn without tension the strength is increased 23%, the strength of the individual fibres being little

affected. It is concluded that when the fibre is allowed to shrink to its full extent no strengthening occurs. The fibres when removed from the yarn, however, are curly, and this suggests that the yarn has shrunk rather than the fibre. By mercerising yarn with tension there is also an increase in strength, but no increase in the fibre strength. In each case bleaching gives rise to an increased strength. The increase varies according to the previous treatments of the yarn. It cannot be concluded, however, that bleaching will always strengthen a yarn, but only that bleaching, properly carried out, will not weaken a two-fold yarn. The fibre strength appears to be considerably reduced—on an average 20%. This, together with the increased yarn strength, points to a greatly increased cohesion of the fibres in the yarn, possibly due to the removal of the natural wax lubricant.

—L. L. L.

Bast fibres; Retting of —. III. P. Kraiss. Z. angew. Chem., 1919, 32, 326–327. (See this J., 1919, 169A, 530A.)

FURTHER experiments on the bicarbonate process of retting carried out on nettles made it clear that nettles sterilised by treatment with chloroform could not be retted, but that on inoculation with a single stem of unsterilised nettle, or with a pure culture of bacteria obtained from the retting liquor of nettles, fermentation set in and retting was complete in 3 days. The retting of nettles takes place rather more rapidly than that of flax, but they are more bulky and require a bath equal to 20 times their weight, whereas flax can be retted with a bath equal to 10 times. Trials were made to substitute chalk for the sodium bicarbonate, but in the case of flax the action of chalk alone was not sufficiently rapid. It was found, however, that the use of chalk permitted a considerable economy in the use of sodium bicarbonate, so that instead of a 0.5% solution of the latter substance a liquor containing 0.5% of chalk and 0.1% of sodium bicarbonate could be used with equal effect. Thus it should be possible on the large scale to perform the retting of 1000 kilos. of flax straw with a bath of 10 cub. m. of water containing 50 kilos. of chalk and 10 kilos. of sodium bicarbonate, the action being completed in 3 days at 35°–37° C., as compared with 5 days required for the ordinary warm water retting process. Moreover, the new alkaline process of retting is practically odourless, whereas the acid retting waters have a most offensive odour.—J. F. B.

Fibres; Substitute — and their manipulation. "Cottonising." E. O. Rasser. Monatsch. Textilind., 1919, 34, 41–43. Chem. Zentr., 1919, 90, IV., 423–421.

"COTTONISING" may be applied to any fibres having a woolly feel, such as jute, hemp, flax, typha, and the like, but chiefly to flax and hemp tows and spinning wastes, as well as to fibres derived from the pulling of rags, twine and cloth wastes, recovered flax and hemp fibres, jute wastes and, lastly, flax and hemp grown for seed. A distinction is made between technical and purely chemical cottonising. In technical cottonising the wastes or fibres are passed through specially constructed tearing willows, and then submitted to a crimping process. A real resolution into ultimate fibres does not occur, and only coarse yarns can be spun which, owing to single projecting hairs, are not so smooth as the chemically isolated ultimate fibres, and therefore cohere more effectively both to each other and to other fibres spun along with them. In the chemical process of cottonising caustic soda and chlorine are employed, also urine, sodium carbonate, and Turkey red oil soaps, further, oxygen or

substances which develop gases. According to a process by Niesytka-Norna, flax straw is decorticated dry by machines and the fibre is then washed in such a manner that the washing fluid is pressed several times with considerable force through the material. Hemp is more easily cottonised than flax. In order to make the cottonised fibre more suitable for spinning, a treatment with a strong cold caustic soda lye is recommended, followed by hot water.

—J. F. B.

Marine fibre [*Posidonia Australis*]. J. Read and H. G. Smith. Commonwealth of Australia Inst. Sci. and Ind., Bull. No. 14, 1919, pp. 60.

MARINE fibre is pale brown in colour, lighter but coarser than coir fibre, to which it bears a general resemblance. The filaments are short in staple (50–200 mm.), and the length of the ultimate fibres is about 1 mm. The mean tensile strength of the filaments is 20.15 kilos. per sq. mm. section, and the elongation 5.29%, but the results are somewhat variable. The filaments are, however, extremely brittle. Chemically, the marine fibre is a highly pronounced lignocellulose, apparently intermediate between jute and wood, but it is characterised by an exceptionally high resistance to the action of dilute alkalis and solvents of cellulose, and by its unusual affinity for dyes, especially basic dyestuffs. *Posidonia* cellulose is obtained with a yield of 55% when the raw fibre is subjected to the chlorination process. The cellulose shows a resemblance to the cellulose of esparto and straw, both as regards length of fibre and its high furfural value. The raw material yields 7.5% of furfural and the isolated cellulose 9.2%. *Posidonia* cellulose, however, does not give colorations with aromatic amines like the cellulose from grasses. Treatment of the cellulose with 17.5% sodium hydroxide solution gave 79.2% of resistant α -cellulose, yielding only 2.9% of furfural. In this respect also it resembles esparto cellulose very closely. It is estimated that 4,600,000 tons of the material is available in the S. Australian deposits, and that the fibre, washed and purified by acid, could be landed at a European port at a cost of £19 per ton. Its shortness, coarseness, and irregularity of staple, the lack of flexibility and cohesion, and the structural characteristics of the filament are all opposed to its employment in the manufacture of fine textiles. For lower grade purposes it might be used as a diluent in admixture with wool, its dyeing properties and low heat conductivity being favourable points. For coarse textiles *Posidonia* fibre is inferior to jute in mechanical properties, but it could be used, and its resistance to chemical and bacterial agencies is advantageous for outdoor work. In so far as the textile inferiority of the material is dependent on the weakness and brittleness of the filaments, a remarkable improvement may be effected by suitable pre-treatment with dilute acids. The flexibility and, to some extent, the tensile strength are increased by steeping the fibre for several hours in 2% nitric acid; other acids have a similar, though weaker, influence. The authors suggest that previous unfavourable reports might be reconsidered with this in view, particularly since the large loss in the carding operation is to be attributed to the lack of flexibility of the filaments in the untreated condition. The authors' investigations have not shown favourable results for the *Posidonia* fibre as a starting point for the manufacture of explosives (compare Smart and Pecover, this J., 1918, 300T). On the other hand, provided a suitable method could be found for the isolation of the ultimate cellulose fibres, the utilisation of *Posidonia* in the paper industry would appear to offer the most promising outlet. The close similarity of *Posidonia* cellulose to esparto cellulose is a strong indication of its suitability as a material for printing papers and the lower grades of writing paper.—J. F. B.

Cellulose and nitrocellulose: absorbent power for gases, and constitution. B. Oddo. Gazz. Chim. Ital., 1919, 49, ii., 127—139.

CELLULOSE absorbs various gases to extents increasing with the solubilities of the gases in water, and absorption of a second gas is accompanied by partial displacement of a gas already absorbed. Both decan- and endeca-nitrated celluloses absorb dry hydrogen chloride and sulphur dioxide. (See also J. Chem. Soc., 1920, i., 16.)—T. H. P.

Nitroacetylcellulose. B. Oddo. Gazz. Chim. Ital., 1919, 49, ii., 140—145.

The preparation and the properties of a mixed acetyl-nitro derivative of cellulose, probably the tetracetyloctonitrate, are described. (See also J. Chem. Soc., 1920, i., 16.)—T. H. P.

Paper pulp; The colouring of — for textile purposes. E. Püschel. Papier-Zeit., 1919, 44, 1742—1743, 1744—1745. Chem. Zentr., 1919, 90, IV., 507—508.

The order of addition to the pulp is first the resin size, then the dyestuff solution, and lastly, after mixing for half-an-hour, aluminium sulphate. If it is desired that the stuff should become warm through prolonged beating, the alum is added shortly before emptying. Mineral colours, and basic and acid dyestuffs, added in the above manner, require no addition of mordant for fixation. In order to avoid uneven dyeing with basic dyestuffs it is advisable to add a little alum to the pulp before the dye. Acid dyestuffs develop their strongest colouring power with heavily sized papers containing 5% of size; their use is not economical in conjunction with weakly sized papers for spinning, and they have to be avoided altogether for unsized cellulose and cellulon yarns. In dyeing with substantive colours sufficient sodium carbonate should be added after the size to give the pulp a neutral or slightly alkaline reaction; the dyestuff solution is then added and 5—10% of Glauber's salt or common salt, calculated on the weight of the fibre, in order to fix the colour; the aluminium sulphate is added last. The quantity of salt used depends on the depth of shade; the water squeezed out of the pulp should not be coloured. Substantive colours are absorbed more readily if the stuff be heated to 50° C. The dyeing of finished paper yarns in dyeing machines has not given satisfactory results; even by prolonged action and the use of penetrating agents the colour does not go through. The best penetration of the dye is obtained by the foam-dyeing treatment.—J. F. B.

Paper pulp; Influence of temperature on the rate of draining of —. S. Smith. Papierfabr., 1919, 17, 1121—1123.

The author has tabulated the values of γ/η representing the ratio of the viscosity to the specific gravity of water at increasing temperatures. He then determined the rate of flow of water at different temperatures through two columns of gravel, fine and coarse. The results showed that the ratio of time of flow to γ/η was a constant for each material at all temperatures, depending only on the size of the particles. On the other hand, when the viscosity law so established was applied to some observed data published by Skark (Papierfabr., Festheft, 1912, 94, 767, and 802) for the rate of draining of variously beaten paper pulps at different temperatures, it was found that the above ratio was not constant, but decreased with increasing temperature. Thus the increased rate of draining of paper pulp on the wire at increased temperatures does not depend only on the change in the viscosity of the water, but is assisted by another factor which, provisionally, may be assumed to be

the shrinkage of the fibres by dehydration and consequently the increase in the size of the capillary passages between them.—J. F. B.

Paper; Quantitative estimation of mixed pulp in newsprint —. Pulp and Paper Mag., 1919, 17, 948—950.

CHEMICAL methods appear to be of little value for the estimation of mechanical and sulphite wood pulps in newspaper, and it is necessary to resort to microscopical methods. Using an accurate sample of the sheet, a careful estimation is made consisting of an average of 10 fields on each of three separate slides. The proportion of sulphite pulp thus estimated is considerably in excess of the percentage by weight actually present, because the cellulose, wood fibre loses 40% of its weight without corresponds to its weight relatively to the ligno-cellulose fibre. In the process of conversion into cellulose, wood fibre loses 40% of its weight without alteration of its dimensions. The difficulty of estimation varies according to the state of preparation of the fibres, the papers of the United States being considerably more beaten, and hence less easily analysed than Canadian papers. As the percentage of sulphite pulp increases the tendency to overestimate it by microscopical inspection is decreased. The following rules have been established as the result of the examination of a large number of mixtures. Scandinavian pulps: In mixtures estimated to contain 50% of sulphite pulp deduct three-tenths of the estimated percentage of sulphite and add this to the mechanical pulp. In mixtures estimated at 65% sulphite deduct one-fourth of this and add it to the mechanical. In mixtures estimated at 80% sulphite deduct one-tenth and add it to the mechanical. Canadian pulps: In mixtures estimated to contain about 42% of sulphite deduct seven-eighths of this and add it to the mechanical pulp. The factor seven-eighths holds good down to 35% of sulphite pulp, but below 35% the factor must be increased as the estimated percentage of sulphite falls. It is considered that an accuracy of 1% in either direction may be attained.—J. F. B.

PATENTS.

Wool, cotton, or like fibres; Machines for drying or carbonising —. J. Charlesworth, Huddersfield. Eng. Pat. 134,100, 11.12.18. (Appl. 20,560/18.)

In a drying or carbonising machine in which heated air is introduced at the bottom and rises through the material, which is fed in at the top and is conveyed through the machine by a series of creeper conveyors, a canopy is fixed over the delivery end in which the hot exhaust gases are collected and then conveyed by a pipe or conduit through the lower part of the machine to the feed orifice of the fan. The hot exhaust gases, mixed with sufficient cold air, are then re-heated and again introduced into the drying chamber.—J. F. B.

[Wool] piece or like scouring processes; Treatment of effluent from —. Distillates, Ltd., and G. G. Jarman, Kirkheaton, Yorks. Eng. Pat. 134,410, 11.12.18. (Appl. 20,559/18.)

THE effluent from woollen piece goods scouring machines is heated to boiling and allowed to cool; the soap from the sodium carbonate contained in the effluent either separates out naturally or is separated by centrifuging or filtering the cold liquor. If necessary the effluent is evaporated to a concentration sufficient to ensure the separation of the soap on cooling. The separated soda liquor is suitable for re-use in scouring.—J. F. B.

Wool and other fibrous substances; Machines used in the washing and scouring of — and for performing similar operations. W. Taylor, Huddersfield. Eng. Pat. 131,714, 5.2.19. (Appl. 2781/19.)

A DEVICE used for the immersion and carrying forward of the fibrous material consists of smooth glazed prongs of earthenware, porcelain, or other vitreous substance, resistant to acids and alkalis, fitted into a slotted bearing and secured by a plate bolted on to the bearing, or fixed by other means so as to be easily replaceable.—S. S. A.

Wool; Process for increasing the durability of —. Farb. vorm. Meister, Lucius, and Brünig, Höchst. Ger. Pat. 299,772, 2.10.15.

WOOL is treated at the ordinary temperature with salts of chromium or aluminium, particularly with the substances which are used in chrome tanning, such as chrome alum, chromium chloride and their basic salts. Alum or aluminium sulphate in the form of neutral or basic salts may also be employed. The treatment of the wool may take place by prolonged steeping or by padding or impregnating with more concentrated solutions, and may be carried out either on the loose wool or on piece goods. The treated wool possesses increased resistance to the action of air and light. (See also this J., 1919, 496A.)—J. F. B.

Silk; Process for degumming — by treatment with water under pressure. Farbenfabr. vorm. F. Bayer und Co., Leverkusen. Ger. Pat. 301,255, 16.1.16.

SMALL quantities of substances with an alkaline reaction are used along with the water. The degumming is satisfactorily performed without the use of soap, and the treated silk possesses the same lustre and feel as that degummed by the usual methods. Suitable alkaline substances are ammonia, sodium carbonate, caustic soda, sodium phosphate, and borax.—J. F. B.

Fabrics for aircraft. F. Sage and Co., Ltd., London, and N. A. T. N. Feary, Peterborough. Eng. Pat. 131,611, 4.11.18. (Appl. 18,064/18.)

PAPER or light textile material, coated on one side with a solution of casein, is applied to each side of an interlaced or woven wire fabric. The whole is compressed so that the paper or textile fabric on one side of the wire is depressed into the interstices between the wire to meet and adhere to that on the other side of the wire. The resulting material may be impregnated with oil or oil varnish or the like under pressure.—S. S. A.

Fireproofing for aircraft. P. R. Bradloy, East Orange, Assignor to Aircraft Fireproofing Corporation, Nutley, N.J. U.S. Pat. 1,321,708, 11.11.19. Appl., 22.3.18.

SEVERAL layers of protective substance, one of which contains alginic acid, are applied to the cloth or wood to be fireproofed.—S. S. A.

Porous substances such as textile fabrics, wood, etc.; Process for preserving —. Grubenholz-impregnierung Ges. m. b. H., Berlin. Ger. Pat. 299,761, 24.10.16.

THE material is treated with fluorosulphonic acid, either as such or as salts of metallic or organic bases, or in mixture with diluting substances, such as sodium sulphate or chloride. In the latter case the two dry salts may be mixed and compressed into tablets. Zinc fluorosulphonate gives a clear solution in water and does not form basic salts. Organic liquids such as creosote may be used as solvents for the fluorosulphonic acid or its salts.—B. V. S.

Non-inflammable fabrics; Process of impregnation for the production of —. W. Naher, Pforzheim. Ger. Pat. 299,773, 27.1.16.

THE fibre before spinning and weaving is sprayed with a solution of sodium stannate, applied in such a way that it dries at the moment of deposition. The impregnated material may then be treated with an aqueous solution of carbonic acid, washed, and dried. The operations may be repeated if necessary. Material so treated retains its normal elasticity, and does not lose its fire-resisting properties by washing.—B. V. S.

Hop-bines; Process for obtaining fibres capable of being spun and a tannin-like material from —. E. Reis, Heidelberg. Ger. Pat. 301,387, 15.9.16.

HOP-BINES are extracted with hot water and then treated with a dilute solution of sodium or potassium hydroxide, sulphite, or bisulphite or magnesium bisulphite, which removes certain pectin substances, leaving others which, by their glutinous properties, serve to strengthen the fibres. From the first aqueous extract, after fermenting and distilling off the alcohol, a tannin-like substance is recovered, which may be used in dyeing and tanning.—B. V. S.

Smooth, stiff vegetable fibres; Process for making — suitable for carding and spinning. M. Bohm und Sohn, Vienna. Ger. Pat. 305,577, 25.1.18.

STIFF, smooth fibres such as kapok, asclepias, and typha fibres are made soft and pliable by treatment with a dilute solution of pyridine bases, washing, and drying.—B. V. S.

Flax and hemp straws; Process for treating —. P. Püschel, Hilvetshof. Ger. Pat. 305,682, 1.11.17.

THE straw, after retting in water, is rinsed with warm water, preferably at 30° C., before being artificially dried, in order to remove as far as possible the viscous retting fluid adhering to the individual stems when they are subsequently pressed between squeezing rolls. In this manner, in spite of the artificial drying, a textile fibre and tow are obtained which are superior in colour and flexibility to the product obtained by natural drying. A higher temperature than 35° C. weakens the fibre under the squeezing operation, while water below 20° C. is not effective in removing the viscous fluid.—J. F. B.

Fibrous plants; Process for loosening the bast of —. Nessel-Anbau-Ges., Berlin. Ger. Pat. 307,144, 2.2.18.

PLANTS such as nettle, ramie, broom, hops, rushes, flax and the like, or portions of such plants comprising the bast, are treated with solutions of sugars under ordinary, reduced, or excess pressure. The use of sucrose, dextrose, maltose, and molasses is specified.—J. F. B.

Fibrous plants, particularly nettles; Process for obtaining the fibre of —. Nessel-Anbau-Ges. Ger. Pat. 312,381, 13.1.16.

THE plants are subjected in thin layers in a closed vessel to the action of superheated steam and then suddenly and strongly cooled. Superheated steam at 200° C. and 0.5 atm. pressure is used at first and is raised subsequently to 300° C. and 3 atm. pressure. The treatment with superheated steam and sudden cooling bring about a rapid and complete separation of the fibres without any deleterious effect on their textile quality.—J. F. B.

Wool substitute from cellulose and similar solutions; Manufacture of —. Glanzfäden A.-G., Petersdorf. Ger. Pat. 312,301, 15.7.19.

ARTIFICIAL filaments from plastic solutions, whilst being freed from the solvents and precipitating

bath chemicals which they contain, are kept under a tension which is induced by the kinetic energy of shower baths directed upon them. For example, spun threads in the form of hanks are carried through a series of chemical and washing shower baths in such a way that the removal of all chemicals takes place in a single passage. The gentle tension thus obtained is sufficient to prevent the thread from giving an opaque and brittle product, and the yarn is strong, soft, bulky, and possesses a slight lustre like wool.—J. F. B.

Cellulose or material containing cellulose; Manufacture of solutions of — A. G. Bloxam, London. From Zellstoff-fabrik Waldhof, Mannheim-Waldhof, Germany. Eng. Pat. 132,815. 12.10.17. (Appl. 14,806/17.)

In making solutions of cellulose by treating the material with a mixture of hydrochloric and sulphuric acids containing less than 39% HCl (Ger. Pat. 306,818 of 1917; this J., 1919, 131 a) a more rapid and complete solution is obtained by previously treating the cellulose with an alkali. For instance, 1 part of cellulose is kneaded with 5 parts of caustic soda solution of 17% strength for half-an-hour; water is then added, the alkaline liquor is separated, the cellulose is washed, scoured, washed again, and dried. The purified cellulose is then dissolved in a mixture containing 35% HCl and 10–12% H₂SO₄.—J. F. B.

Cellulose acetate; Manufacture of compositions, preparations, or articles having a basis of — H. Dreyfus, London. Eng. Pat. 133,353, 29.4.18. (Appl. 7193/18.)

Pure toluene-*o*-monomethylsulphonamide and pure toluene-*p*-monomethylsulphonamide are solid at the ordinary temperature, and are unsuitable as plastic-inducing solvents. Mixtures of toluene-*o*-monomethylsulphonamide or toluene-*o*-monoethylsulphonamide with some of the corresponding para-compounds are, however, suitable for this purpose. They may be used with or without triphenyl or tri-cresyl phosphate and monomethylurea, etc., for the production of plastic cellulose acetate products. —L. L. L.

Cellulose [acetate] compound; Non-inflammable — W. G. Lindsay, Newark, N.J., Assignor to The Celluloid Co. U.S. Pat. 1,319,229, 21.10.19. Appl., 9.3.18.

ACETYLCELLULOSE is mixed with phenyl salicylate and a solvent common to both.—J. F. B.

Celluloid, vulcanite, or the like; Substitutes for — W. T. Robinson-Bindley, A. W. Weller, and E. Dulcken, London. Eng. Pat. (a) 134,564 and (b) 134,565, 27.2.18. (Appls. 3502 and 3503/18.)

(a) An infusible celluloid or vulcanite substitute, insoluble in acids, spirits, oils, or petrol, is obtained by condensing *o*-, *m*-, or *p*-cresol with formaldehyde or an equivalent quantity of a substance adapted to yield formaldehyde, in the presence of a neutral sulphate at 60°–90° C. according to whether a soft or hard product be desired. The reagents (7 parts by weight of cresol and 5 parts by weight of formaldehyde) may be brought together in the gaseous form, preferably under a pressure of 10–20 lb. per sq. in., the cresol being volatilised by a current of steam, and sufficient sodium sulphite being packed into the reaction tube to ensure contact with the reacting gases. Alternatively, formaldehyde, 50 parts, or volatilised paraformaldehyde may be blown into *o*- or *m*-cresol, 50 parts, maintained at 60° C. in the presence of 5–10 parts of the catalyst dissolved in a small quantity of the formaldehyde solution until a treacly mass is formed. The material may be hardened by heating in an autoclave at

140°–160° C. at a pressure of 200 lb. per sq. in., or on the water-bath at 60°–80° C. without pressure. Fillers may be incorporated with the material whilst it is still in the semi-molten condition prior to its being placed in the hardening moulds. (b) Substitutes for celluloid, vulcanite, or the like are obtained by incorporating camphene and nitrocellulose or cellulose acetate or mixtures of these or of camphene and celluloid with the material obtained by any known process for the condensation of phenol or cresols (without separation of the individual cresols) with formaldehyde or by the processes described under (a) or in Eng. Pat. 134,563 (page 35 a).—A. de W.

Pyroxylin composition and process of making same. W. F. Doerflinger, Staten Island, N.Y. U.S. Pat. 1,320,458, 4.11.19. Appl., 6.12.18.

A COATING composition is made with a non-drying oil and pyroxylin dissolved in a volatile solvent containing diacetone-alcohol, *n*-butyl alcohol, a volatile ketone, and benzene.—J. F. B.

Pyroxylin solvent and composition containing the same. E. M. Flaherty, Parlin, N.J., Assignor to E. I. du Pont de Nemours and Co., Wilmington, Del. U.S. Pat. 1,321,611, 11.11.19. Appl., 16.3.18. Renewed 24.6.19.

A NITROCELLULOSE composition is treated with a solvent consisting of a mixture of ethyl acetate, butyl alcohol, and benzene.—S. S. A.

Pyroxylin bodies; Process of producing — Solvent for pyroxylin bodies. M. V. Hitt, Parlin, N.J., Assignor to E. I. du Pont de Nemours and Co., Wilmington, Del. U.S. Pats. 1,321,633 and 1,321,634, 11.11.19. Appl., 10.12.17. Renewed 24.6.19.

PYROXYLIN is dissolved in a mixture of ethyl acetate, benzene, and ethyl alcohol, and the solvent mixture is evaporated.—S. S. A.

Millboard or the like; Process for impregnating articles of — to render them waterproof. Apparatus for impregnating articles of pulp- or straw-board. E. Slight and A. D. Lacy, London. Eng. Pats. 134,010 and 134,176, 21.10.18. (Appls. 17,165/18 and 12,880/19.)

THE articles are first partially impregnated with a solution of casein, to which formaldehyde may be added if desired, in order to stiffen them and economise the consumption of the waterproofing composition, subsequently applied in the form of a mixture of wax and resin. In some cases the casein may be combined in the same bath with the wax and resin. The articles after immersion in the bath are carried by a conveyor from one end to the other of a heated impregnating chamber, wherein the superfluous solution is collected and returned to the bath. The chamber is heated by means of a furnace, the products of combustion from which pass through a flue in the inclined hollow bottom of the impregnating chamber, throughout its entire length, and thence through uptakes into the chamber itself. The gas-heated impregnating bath is situated at the lower end of the inclined chamber, and the products of combustion from this are likewise delivered into the chamber. The endless conveyor is preferably constructed of metal slats, the edges of which are turned over and joined together by wire links to form an endless band.—J. F. B.

Paper; Apparatus for making — J. T. Murphy and E. J. Raney, Assignors to J. L. Carey, Chicago, Ill. U.S. Pat. 1,318,900, 14.10.19. Appl., 30.1.19.

Two heating engines are provided at different levels, the lower one being operated intermittently

and the higher one continuously. A stuff-chest, having a capacity greater than that of the intermittent bending engine, is situated at an intermediate level, and means are provided for conveying stock from the intermittent engine to the stuff-chest and from the stuff-chest to the continuous bending engine.—J. F. B.

Paper; Process of removing mineral matter from — V. Nakamura, Assignor to Nippon Sen-I Kogyo Kabushiki Kaisha, Tokyo. U.S. Pat. 1,318,902, 14.10.19. Appl. 9.7.18.

PAPER is subjected to the action of a solvent consisting of *aqua regia* containing an excess quantity of nitric acid and hydrofluoric acid for the removal of mineral matter.—J. F. B.

Paper pulp; Process and apparatus for treating — G. C. Howard, Tacoma, Wash. U.S. Pat. 1,322,489, 18.11.19. Appl. 8.5.17.

A dilute mixture of pulp and water is caused to impinge upon the lower part of one side of a pair of rapidly rotating rolls disposed within a vat of semi-circular cross-section, whereby the pulp is drawn between the rolls and a homogeneous mixture is discharged at the opposite side of the vat.

—W. E. F. P.

Paper-yarn; Process for strengthening — O. Ruff, Breslau. Ger. Pat. 302,551, 6.7.17.

THE paper, before spinning, is soaked in a previously heated solution of crude cresol, formaldehyde and some alkali, either on the spinning machine or in a separate process. A larger proportion of alkali is required for a sulphite-pulp than for a sulphate-pulp paper. After spinning, the yarn or the material woven therefrom is heated for some time at 80°–110° C.—B. V. S.

Paper, fabrics, and the like; Process for the sizing, waterproofing, dressing, etc. of — W. Schmidt, Elberfeld, and E. Heuser, Darmstadt. Ger. Pat. 305,525, 12.7.17.

THE paper pulp or the fabric is treated with tar from lignite or bituminous coal either in a fine state of division or in the form of a tar soap from which the tar is precipitated on the fibres by the addition of acid, formaldehyde or the like. The adhesion of the tar to the fibre can be increased by the addition of resin, casein, or animal size. The tar can be resinated by the action of formaldehyde etc., and the coloration of the paper pulp can be modified by bleaching agents.—B. V. S.

Paper; Process for sizing — by the aid of montan wax. P. Klemm, Gautzsch. Ger. Pats. (a) 305,678, 12.1.17, and (b) 310,076, 8.5.17.

(a) A STABLE emulsion of montan wax, suitable for sizing paper, is obtained by heating it with a small quantity of resin soap or naphthenic acid soap in alkaline solution. (b) Liquid resin (*Tallol*) obtained from soda-cellulose waste lyes (this J., 1916, 1163) is saponified and used as the emulsifying agent, somewhat less than 25% of the quantity of montan wax being required.—B. V. S.

Paper and the like; Process for sizing — Feldmühle Papier und Zellstoffwerke A.-G., Berlin. Ger. Pat. 307,087, 30.11.17.

FIBROUS materials or finished products prepared from them are treated with solutions of the organic matter (lignin) from waste sulphite liquors rendered precipitable by treatment with alkalis, and the size is precipitated on the fibre by the addition of acids or suitable salts. The lignin size may be used in admixture with other known paper-sizing agents. By heating with alkalis the sulphonic group is almost completely eliminated from the lignin-sulphonic acid and a dark brown alkaline solution

of lignic acid is obtained, which gives a voluminous precipitate with acids or salts. About 10–20% of caustic soda, calculated on the dry substance of the sulphite waste liquor, is required. Alternatively, the alkaline liquor may be neutralised with acid, precipitated by alum or kieserite, and used for sizing in the proportion of 2 —J. F. B.

Paper; Manufacture of hard-sized — O. Ruff, Breslau. Ger. Pat. 313,112, 25.1.18.

PAPER prepared with the addition of vegetable mucilages or with substances capable of yielding mucilages, or paper made from pulp which has previously been treated with acids or acid salts (see Ger. Pats. 309,999, 311,772, and 312,179; this J., 1919, 281A, 625A, 896A) is subjected to a heating treatment. Example: About 10–30% of powdered peat calculated on the dry substance is added to the pulp in the hollander, and after the paper has been made it is heated at 120° C. for about 2 hours.

—J. F. B.

Cleaning or polishing material [*"Putzwolle"*]. Reis and Co., Friedrichsfeld. Ger. Pat. 303,302, 26.5.17.

WASTE from paper industries, more particularly from paper spinning and weaving, is softened and made absorbent by treatment with alkalis, inorganic or organic acids, sulphurous acid, or chlorine compounds, and then bleached and worked up into "cleaning waste" in the usual way.—B. V. S.

Coating or impregnating material; Method and apparatus for continuously — O. Minton, Short Hills, N.J. U.S. Pat. 1,322,327, 18.11.19. Appl., 22.7.19.

MATERIAL in the form of a strip is passed over rollers into and through a liquid seal which has no action on the material. The liquid seal is in the form of a U-tube and forms the inlet to a vacuum chamber through which the material then passes over guide rollers. The material passes out of the vacuum chamber through another U-tube containing the coating or impregnating material.

—W. F. F.

Waste liquors from cellulose manufacture or other similar waste liquors; Dry distillation of — with strong bases in the presence of steam. E. L. Rinman, Djursholm, Sweden. Eng. Pat. 120,721, 30.10.18. (Appl. 17,718/18.) Int. Conv., 8.11.17.

WASTE liquors from the manufacture of cellulose from wood, straw, or other materials by the soda process, waste liquors produced by boiling vegetable matters with caustic soda until the cellulose is dissolved, or waste liquors from sulphite pulp manufacture, after boiling with lime, are mixed with suitable proportions of caustic soda and lime, the mixture is concentrated by evaporation until it contains about 25% of water and then subjected to destructive distillation, preferably by means of hot gases in the presence of superheated steam. The temperature is maintained below 200° C. until the water has been substantially driven off, then between 200° and 300° C. until ammonia, wax, and methyl alcohol have distilled over, and, lastly, between 300° and 500° C. during the formation of acetone and, later, of light oils and heavy oils. The proportions of bases to be added per 100 parts of organic matter range between 10 and 65 parts Na₂O and between 30 and 40 parts CaO.—J. F. B.

Lyes from soda- or sulphite-cellulose process; Dry distillation of waste — E. L. Rinman, Stockholm. Ger. Pat. 313,607, 1.9.15.

THE use of milk of lime instead of finely-powdered slaked or quicklime results in a 30% increase in the yield of acetone. Waste lye from the soda-

cellulose process, for example, is concentrated to 30° B. (sp. gr. 1.26) and mixed with a quantity of milk of lime corresponding to 400 kilos. CaO per 1000 kilos. wood. This mixture is concentrated to 55° B. (sp. gr. 1.62) and then distilled with superheated steam, the temperature being slowly raised to 500° C. The yield is about 40 kilos. of acetone and 50 kilos. of oil per 1000 kilos. of wood.—W. P.

Lignin substances insoluble in acids and suitable for sizing paper; Process for obtaining — from the ligninsulphonic acids of sulphite-cellulose waste lyes. Feldmühle Papier und Zellstoffwerke A.-G., Berlin. Ger. Pat. 307,663, 27.1.18. Addition to Ger. Pat. 307,087 (see preceding abstract).

THE liquor containing the ligninsulphonic acids is poured into a hot concentrated caustic alkali solution and the mixture heated until the interaction is complete. The reaction is quicker, more certain and more convenient in operation in this way than if the alkali solution is added to the sulphite liquor. The lignin substances are separated from the resulting solution by treatment with acid, and are redissolved in alkali for use in paper-sizing.

—B. V. S.

Paper-pulp; Machines for straining —. Watford Engineering Works, Ltd., and J. Paramor, Watford. Eng. Pat. 134,923, 13.11.18. (Appl. 18,587/18.)

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

Vegetable fibres; Elimination of nitrogen from — in the bleaching process. S. H. Higgins. J. Soc. Dyers and Col., 1919, 35, 164—169.

By repeatedly distilling 30 grms. of air-dried yarn in a liquor containing 4% of caustic soda on the weight of material and titrating the ammonia evolved with N/10 sulphuric acid, American and Egyptian cotton yarn and linen yarn were found to contain 0.180, 0.275, and 0.420% of nitrogen respectively. Comparing the protein values calculated from these results with the figures given by Osborne for typical proteins, the author infers that the nitrogen in cotton is not all present as protein and that the elimination of proteins from textile fibres during bleaching cannot be measured by simple nitrogen determinations. Lime hydrolyses

the proteins, giving results similar to those obtained with caustic soda. American yarn was subjected to treatments imitative of large-scale bleaching operations, then well washed and distilled with sodium hydroxide. It was found that the yarn was freed almost completely from protein nitrogen by boiling with caustic soda or soda ash, but that of the residual 8.3% of nitrogen practically none was removed by a second alkali boil. The products of lime hydrolysis are only partly soluble and resist removal by washing with water. In the case of linen the proteins are removed effectively by caustic soda or scouring (i.e., lime boil, sour, and soda ash boil), but only partially by soda ash. The author therefore maintains that, contrary to the statement of Cross, Bevan, and Briggs (this J., 1908, 262), cotton or linen when scoured with caustic soda or with lime boil, sour and soda ash boil, are incapable of forming chloramines on treatment with bleaching-powder solution because they no longer contain appreciable quantities of proteins.—S. S. A.

Permanganate; Bleaching with —. W. Kind. Z. ges. Textilind., 1919, 22, 246—247, 255—256. Chem. Zentr., 1919, 90, IV., 412.

IN bleaching with permanganate it is necessary to work in acid solution, using sulphuric acid and on no account hydrochloric acid, which develops free chlorine and attacks the cellulose very severely. The alkalinity may be reduced by magnesium sulphate, but its action is not quite satisfactory, and in some cases the strength of the bleached goods is impaired; moreover, the oxygen is not so completely utilised as in an acidified bath. Strong standing baths of permanganate are dangerous, since local attacks on the fibre may be induced by residues of alkali.—J. F. B.

Active oxygen in bleaching and laundry preparations; Efficiency of —. A. Grün and J. Jungmann. Seifenfab., 1919 39, 69—73. Chem. Zentr., 1919, IV., 90, 757—758.

THE authors have worked out a method for the determination of the loss of active oxygen in laundry processes, and the efficiency of the methods of treatment can thus be established. The active oxygen remaining in the liquid after use can be determined by permanganate, and this added to the amount of gaseous oxygen generated by the treatment shows the total consumption as compared with the quantity of active oxygen originally present. The method of estimation consists in treating a fabric in a special apparatus (this J., 1918, 729A) with the solution of the bleaching agent and collecting and measuring the gaseous oxygen evolved. In one set of trials a preparation consisting of a mixture of soap, soda, sodium silicate and perborate was used, the solution containing 0.005% of active oxygen. It was important to establish the influence of the hardness of the water. For this purpose an unbleached, raw cotton fabric was used and trials were carried out with waters ranging from 0° to 14° (German) hardness. The direct losses of active oxygen were found to be inversely proportional to the hardness of the water. With almost completely softened water the loss amounts to one-half or more; with waters of 3°—6° of hardness it is from one-fourth to one-third, and with harder waters it becomes negligible. If, however, any traces of heavy metals or other foreign matters are present, the losses are considerably larger. The consumption of active oxygen by the fabric is comparatively independent of the hardness of the water. Experiments with dirty fabrics also showed that the loss of active oxygen was considerably greater when using soft water than with hard waters. In the case of soft water the active oxygen was always practically completely discharged,

whether clean or dirty cloth or no cloth at all was used. The constituents of hard waters stabilised the perborate, so that in blank experiments the major portion of the active oxygen remained in the bath, and with clean or fairly clean fabrics about one-third remained; only in the case of dirty goods was practically the whole of the oxygen discharged. Of this total quantity two-thirds was utilised, and one-third was lost. The liberation of part of the active oxygen in the form of gas is regarded as an unavoidable side-reaction which runs parallel with the bleaching action. From the difference between the oxygen consumption of dirty and clean fabric, the true efficiency of the oxygen consumption by the dirt was found to be about 20%.

—J. F. B.

Chromed dyeings; Fastness to fulling of —. A. Reyl. *Färber-Zeit.*, 1919, 30, 237—238.

COMPLAINTS are sometimes made in connection with dyestuffs intended to show good resistance to fulling when dyed on wool after-treated with chromium, and it is found that the colour bleeds out during the fulling operation. The cause of the trouble generally lies in the material to be dyed. For instance, re-manufactured wool is very frequently present in large quantities, and if this material has previously been dyed with a colour which is not fast, it will not be fast to fulling even when topped with the mordant dyestuff. The material should be tested by vigorously washing a piece with sodium carbonate or soap, and if any of the colour comes out of the shoddy, it must be treated before dyeing with the chrome dyestuff. Such treatment may consist in working the goods in a lukewarm bath of sodium carbonate until no more colour bleeds out in the test. Preferably, however, since the alkali damages the fibre, the colour of the shoddy should be taken out by a stripping agent. The goods must then be thoroughly rinsed before dyeing. The use of a stripping agent instead of soda presents the advantage that it leaves the goods much lighter in colour and capable of taking clearer and paler shades. If the fault cannot be traced to the presence of shoddy, the defective fastness of the chrome-mordanted wool to fulling may be due to the presence of grease, owing to the goods having been insufficiently scoured. The grease obstructs the penetration of the dye solution into the fibre and causes the colour to be deposited only superficially; such unfixed dyestuff will readily come out during fulling.—J. F. B.

Strength of cotton. Greenwood. See V.

Colouring paper pulp. Püschel. See V.

PATENTS.

Bleaching; Composition for and process of —. J. F. King, Assignor to H. B. Haines, Philadelphia, Pa. U.S. Pats. 1,321,643 and 1,321,644, 11.11.19. Appl., 28.6.19.

The goods to be bleached are introduced into a solution of sodium chloride, potassium hydroxide, sodium carbonate, and hydrogen peroxide in water, the temperature is raised, and the bleached material is subsequently rinsed.—S. S. A.

Silk; Method of loading —. Deutsche Gasglühlicht A.-G. (Auerger), Berlin. Eng. Pat. 116,102, 22.5.18. (Appl. 8517/18.) Int. Conv., 22.5.17.

The fibre is dried at a low temperature, after saturating with tin chloride and centrifuging, and treated with alkaline gases, such as ammonia or methylamine. In order to avoid damage to the silk the gases may be diluted with air or indifferent gases. The loading thus obtained is two and a half times as much as that usually obtained. The rinsing baths are clear and without precipitate. The loaded fibre may be further treated in known

manner with phosphates and silicates, and the handle, lustre, and firmness of the silk are the same as are obtained by the usual process. Tin salts may be replaced by other salts, for example, chromium salts.—L. L. L.

Dyeing certain colours on vegetable fibres, yarns, and fabrics. V. H. Gatty, Preston. Eng. Pat. 133,620, 16.4.19. (Appl. 9708/19.)

The material is impregnated with solutions of salts of copper and manganese, dried by hydro-extraction, squeezing rollers, or the like, and then passed through a hot alkaline bath. The alkaline bath may consist of hydroxides, silicates, or carbonates of sodium and potassium, either singly or in combination. The shades range from pale olives, yellow browns and fawns, deep olives, tobacco browns, to full dark chocolate shades.—L. L. L.

Sulphonic acids of xylene and solvent naphtha; Utilisation of — [for production of foam baths for dyeing]. Meister, Lucius, u. Brüning, Höchst. Ger. Pat. 312,867, 4.5.17.

The sulphonic acids of higher aromatic hydrocarbons or the resinous substances obtained by the action of sulphuric acid and formaldehyde on these hydrocarbons may be used to promote the production of foam baths for dyeing. The viscous, tough or hard resinous masses are easily sulphonated in the cold with weak oleum. The sodium sulphates are soluble in water, and the solutions form an abundant and tenacious froth. This occurs not only with neutral and alkaline solutions, but also with acid solutions. To produce a good foaming dye bath, about 5 grms. per 1 litre of liquor is necessary.—H. J. H.

Hop-bines. Ger. Pat. 304,387. See V.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Chlorine cells [Electrolytic] —. F. G. Wheeler. Chem. and Met. Eng., 1919, 21, 436—438.

As the cheapest and most adaptable cell the author adopted a type of the form used by Hargreaves in 1894, cylindrical in shape and built so that the entire exterior surface is the cathode. To minimise plugging and capillary action of the diaphragm, a thin sheet diaphragm was devised which gave an efficiency approximating to unity over long periods of time. This cell can be shut down without damage, because, on re-starting, as the cell becomes warmer the viscosity of the brine decreases and it flows readily through the diaphragm, removing the ferric hydroxide precipitated in the pores of the diaphragm by the stoppage. Steam blown into the cathode compartment keeps the cell hot, thus promoting the flow of brine through the diaphragm, reducing the concentration of the hydroxyl ions, and thereby increasing the efficiency of the cell, but its use is not economical if power is cheap, on account of the cost of re-concentrating the solution, which becomes diluted by condensed water.—S. S. A.

Bucher process [for the fixation of nitrogen]; Equilibrium conditions in the —. J. B. Ferguson and P. D. V. Mannig. J. Ind. Eng. Chem., 1919, 11, 946—950.

The reaction which takes place on heating a mixture of sodium carbonate, carbon, and iron in an atmosphere of nitrogen in Bucher's process (this J., 1917, 451) is represented by the equation— $\text{Na}_2\text{CO}_3 + 4\text{C} + \text{N}_2 \rightleftharpoons 2\text{NaCN} + 3\text{CO}$. Since it is probable that the equilibrium constants in the reaction cannot be experimentally determined, an attempt has been made to determine certain

empirical relations which may be regarded as a measure of the actual conditions of equilibrium. For this purpose determinations were made of the variations in the amounts of alkali in a charge which at the equilibrium point was converted into cyanide, with known variations in the stream of gas passing over the charge. Experiments at 950°–1000° C. with concentrations of carbon monoxide up to 80% did not cause any change in an iron boat in which the charge was placed, which confirmed the statement of Hilpert and Dieckmann (this J., 1915, 964) that iron is stable at these temperatures in the presence of equilibrium mixtures of carbon monoxide and dioxide. The percentages by weight of sodium carbonate converted into cyanide in the series of experiments were plotted against the carbon monoxide content of the original gas, it being assumed that no great error is introduced by unknown reactions of the carbon monoxide at very high or very low concentrations. From the curves thus obtained the following deductions with regard to commercial cyanide nitrogen-fixation processes were drawn: The temperature has relatively little influence upon the possible yield of cyanide in the case of low concentrations of carbon monoxide, but would have considerable influence if producer-gas containing e.g. 30% CO were used. Using producer-gas, a conversion up to 63% can be obtained at 1000° C., and this yield would probably be increased by raising the temperature. The presence of 15% carbon monoxide in the initial gas mixture reduces the amount of conversion by 30% compared with that given by pure nitrogen, whilst 60% reduces it by 50%. If the initial gas contains relatively large amounts (25–30%) of carbon monoxide slight variations in the proportions of that constituent have little effect upon the yield. It is probable that the controlling reaction in the Bucher process is the primary reduction of the sodium carbonate by carbon to form sodium, and the effect of the carbon at this stage may be merely to ensure that the carbon dioxide pressure is maintained well below the dissociation pressure of the carbonate.

—C. A. M.

Ammonium sulphate and potassium nitrate; Production of — from potassium salts. H. Hampel. Chem.-Zeit, 1919, 43, 617–619, 634–636.

The author outlines two continuous processes for the manufacture of ammonium sulphate by utilisation of the combined sulphuric acid present in the vast quantities of German potassium salts which are available. In the first process, in which ammonia and synthetic nitric acid are utilised, the reactions are explained by the equations: (1) $K_2SO_4 + Ca(NO_3)_2 = 2KNO_3 + CaSO_4$; (2) $CaSO_4 + 2NH_3 + CO_2 + H_2O = CaCO_3 + (NH_4)_2SO_4$; (3) $CaCO_3 + 2HNO_3 = Ca(NO_3)_2 + CO_2 + H_2O$. The by-products, such as potassium nitrate, obtained in this process are more valuable than the initial materials. In the second process ammonium sulphate and magnesium oxide are produced and the following reactions occur: (1) $MgSO_4 + CaCl_2 = MgCl_2 + CaSO_4$; (2) $CaSO_4 + 2NH_3 + CO_2 + H_2O = CaCO_3 + (NH_4)_2SO_4$; (3) $CaCO_3 + 2HCl = CaCl_2 + H_2O + CO_2$; (4) $MgCl_2 + H_2O = MgO + 2HCl$. A description of suitable plant is given. Comparisons of estimated costs of these processes with the cost of the ordinary process using sulphuric acid are quoted.

—W. J. W.

Calcium carbide; Action of bromine on —. E. Barnes. Chem. News, 1919, 119, 260–261.

4.5 GRMS. of finely-powdered calcium carbide left in contact with 45 grms. of dry bromine in a 50 c.c. sealed bottle for five months gave a product which, after removal of excess of bromine, weighed

32.4 grms. and contained 22 grms. of hexabromoethane, 8.8 grms. of calcium bromide, and 0.2 gm. of unchanged carbide. Calcium carbide and bromine heated in sealed tubes to 100° C. until no further action was apparent produced carbon and calcium bromide. Dry chlorine was found to have no action on calcium carbide exposed to it at the ordinary temperature for two months.

—S. S. A.

Sodamide; Autoxidation of —. H. Schrader. Z. anorg. Chem., 1919, 108, 44–48.

WHEN exposed to air the amides of the alkali metals undergo autoxidation with formation of nitrite, hydroxide, and ammonia. When finely-divided sodamide is exposed to air in presence of a little water a yellowish-red product is formed, which has now been shown to be a peroxide, probably of the formula $NaNH_2O_2$. After 58 days a sample was found to contain 0.44 mol. % of peroxide and 6.9 mols. % of nitrite calculated on the sodamide taken. The analysis was carried out by adding the product to a saturated solution of barium chloride and filtering off the precipitated barium peroxide, the nitrite being determined in the filtrate. In dry air autoxidation does not take place at the ordinary temperature, but at 100°–110° C. it proceeds slowly, 9.5 mols. % of peroxide being formed in the course of 170 hours. The peroxide is stable in dry air, but in moist air is changed into a white substance, the aqueous solution of which gives the peroxide reaction.

—E. H. R.

Barium nitrate; Reduction of — by the alternating current. P. Wenger and A. Lubomirski. Ann. Chim. Analyt., 1919, 1, 339–342.

THE reduction of barium nitrate in aqueous solution increases with the amperage of the alternating current, except when mercury electrodes are used, in which case a maximum yield of nitrate is obtained with 0.6 amp. Increase of temperature increases the yield with lead electrodes, decreases it with aluminium and zinc electrodes, and has but little effect in the case of copper, cadmium, or magnesium electrodes. Using mercury electrodes and a current of 0.4 amp., 71% of the nitrate is reduced in 5 hrs. The oxygen liberated from the nitrate combines with the electrodes forming suboxides (in the case of copper, mercury, cadmium, or tin electrodes), hydroxides (with lead, zinc, aluminium, or magnesium electrodes), or oxides (with nickel or silver electrodes). Modification of the surface of the electrodes affects the yield of nitrite. The metallic electrodes do not in themselves reduce the barium nitrate.—W. P. S.

Ferrocyanides; Electrometric method for the determination of — depending on a change in oxidation potential. G. L. Kelley and R. T. Bohn. J. Amer. Chem. Soc., 1919, 41, 1776–1783.

SOLUTIONS of ferrocyanides may be estimated by titration with potassium permanganate in the presence of sulphuric acid, using the sudden change in EMF observed with a bright platinum electrode to mark the end point. About 1 gm. of potassium ferrocyanide in 250 c.c. of water is treated with 2.5–5.0 c.c. of sulphuric acid (sp. gr. 1.58) and titrated with 0.05N potassium permanganate, using an electrometric apparatus which will indicate changes of potential of one millivolt. A small precipitate may form during the titration, but this will re-dissolve. The titration should be performed slowly with mechanical stirring. As the end point is approached the permanganate should be added drop by drop and time allowed for the completion of the reaction. The end point is taken as the point of greatest change in potential for equal additions of permanganate. Should too much perman-

ganate be added, the end point may be approached from the other side by adding a standard solution of ferrocyanide. The presence of ferricyanides does not interfere with the titration, nor do amounts of chloride up to 1 gm. of sodium chloride. Any salts which under the conditions of experiment produce a precipitate with either ferrocyanide or ferricyanide seriously interfere with the method.

—J. F. S.

Aluminium phosphate; Soluble —. O. Svanberg. Z. anorg. Chem., 1919, 108, 70—72.

WHEN a few drops of a 1—2% solution of potassium dihydrogen phosphate are added to a neutral solution of aluminium chloride, both being previously coloured yellow by the addition of a drop of methyl orange solution, the colour of the mixture immediately becomes red without the formation of any precipitate or turbidity. On warming aluminium phosphate is precipitated, but there is no further colour change. It is shown that the hydrogen ion concentration for mixtures of the two salts reaches a maximum with about 40 mols. % KH_2PO_4 , this accounting for the colour change. Salts of calcium, magnesium, zinc, or cadmium do not give the reaction. Beryllium sulphate behaves like aluminium chloride, but is more sensitive to excess of the phosphate.—E. H. R.

Permutit; Basic exchange in —. V. Rothmund and G. Kornfeld. Z. anorg. Chem., 1919, 108, 215—225.

THE previous work (this J., 1918, 559 A) has been extended to include cases of exchange between divalent and trivalent ions in permutit. For the case of divalent ions the exchange was studied between copper-permutit and the nitrates of magnesium, calcium, strontium, and barium. The equilibrium is independent of dilution, and the tendency to permutit formation increases with the atomic weight of the metal. When the exchange is between ions of different valency, as between silver-permutit and barium nitrate or lanthanum nitrate, dilution has considerable influence on the equilibrium. (See also J. Chem. Soc., Jan., 1920.)

—E. H. R.

Kaolinite and other silicates; Constitutional formulae of —. R. Wegscheider. Z. Elektrochem., 1919, 25, 352.

THE constitution of polysilicates is such that the silicon atoms are never directly combined, but always combined through oxygen. (See also J. Chem. Soc., Jan., 1920.)—J. F. S.

Lead oxides; Determination of volatile matter in —. O. Andersen. J. Amer. Ceram. Soc., 1919, 2, 782—783.

IF the oxide contains no appreciable amount of metallic impurities a weighed amount is mixed with ground quartz which has previously been calcined at 100°C ., in the proportion of 3 parts of PbO to 1 part of silica, and placed in a narrow platinum crucible. A thin layer of silica is placed on top and the crucible with its contents is weighed, ignited at 800°C . for 26 mins. and then at 1000°C . for 15 mins. The eutectic formed melts nearly 100°C . below the melting point of pure lead monoxide (880°C .), and does not attack platinum. The crucible is covered, allowed to cool, and is then re-weighed, the loss being the volatile matter present in the lead oxide. The amount of pure PbO is found by difference.—A. B. S.

Arsenic trichloride; Action of acetylene on —. O. A. Dafert. Monatsh. Chem., 1919, 40, 313—323.

ACETYLENE does not react to any considerable extent with arsenic chloride at the ordinary temperature

or at the boiling point of the latter; in the presence of anhydrous aluminium chloride at the ordinary temperature, however, diacetylene arsenic chloride, $\text{AsCl}_3 \cdot 2\text{C}_2\text{H}_2$, is readily formed as a heavy yellow oil, sp. gr. 1.6919 at 15°C ., b.p.t. 250°C . The vapours are strongly irritating but not markedly poisonous, though exhibiting strong bactericidal power. When compared with the corresponding aluminium and antimony compounds, the arsenic derivative exhibits a remarkable stability, since it can be distilled and is not decomposed by water. It evolves acetylene when heated with potassium hydroxide solution. At a higher temperature arsenic trichloride and acetylene in the presence of aluminium chloride yield a black, organo-arsenic compound of high molecular weight, which is very stable towards reagents but sensitive to light, and which, in its properties, resembles the aluminium derivative prepared by Baud in a similar manner.

—H. W.

Bromine in mineral waters and brines; Determination of —. W. F. Baughman and W. W. Skinner. J. Ind. Eng. Chem., 1919, 11, 951—959.

THE water or brine, rendered alkaline if necessary with sodium carbonate, is evaporated to dryness, and the residue transferred to a reaction vessel which is connected to two absorption vessels, the first containing 20 c.c. and the second 5 c.c. of a solution of 1 gm. of sodium sulphate and 0.2 gm. of sodium carbonate in 25 c.c., in each case diluted to 200 c.c. The reaction vessel contains glass beads and the residue from the mineral water is distributed over these. After the introduction of a solution of 15 grms. of chromic anhydride in 10 to 12 c.c. of water, the evaporation basin is washed out with water, and the washings (about 25 c.c.) also introduced. Air is then aspirated through the apparatus until the saline material in the reaction vessel is in solution, when the apparatus is closed, and allowed to stand overnight. A current of air (about 0.25 to 0.5 litre per min.) is then drawn through it for 3 hours, while four successive portions of 2 c.c. each of 3% hydrogen peroxide are added at intervals of 30 mins. (to accelerate the evolution of bromine). The contents of the two absorption vessels are evaporated nearly to dryness, and the residue returned together with 25 c.c. of water to the reaction vessel, which has meanwhile been cleaned and recharged with glass beads and 15 grms. of chromic anhydride. The two absorption vessels are charged with 10 grms. and 3—4 grms. respectively of potassium iodide in 200 c.c. of water, a slow current of air drawn through the apparatus for about 1 hour, and the liberated iodine titrated. In the first aspiration the bromine becomes concentrated, whilst in the second treatment with chromic anhydride so little chlorine is present that pure bromine is evolved. (See also J. Chem. Soc., Jan., 1920.)—C. A. M.

Hydrogen of high purity; Preparation and testing of —. J. D. Edwards. J. Ind. Eng. Chem., 1919, 11, 961—963.

THE apparatus shown in the diagram obviates the drawbacks of the ordinary Kipp generator. Pure hydrogen is at once obtained and fresh acid can be introduced without admitting air. The apparatus is exhausted through *a*, whilst the tube, *d*, which dips into mercury, serves as an indicator of the residual pressure and as a safety valve. The acid flask, *f*, is nearly filled with sulphuric acid (1.8) and a few fragments of zinc, so that the hydrogen evolved will sweep out all air. The vent *c* is then closed until the pressure of the gas is sufficient to force the acid into the tube, to free the connections from air. The tube beyond the tap, *b*, enters the generator through a rubber stopper

which is always under liquid. The rate of generation of the gas is controlled by the tap, *c*. Tests made by means of the interferometer (this J., 1915,

638) in comparison with pure hydrogen derived from the electrolysis of barium hydroxide, showed that the hydrogen generated by this apparatus contained less than 1:10,000 parts of impurities. Weaver's colorimetric test for acetylene (this J., 1916, 347) indicated not more than 1 or 2 parts per million. No arsenic or antimony was found. Tests of the hydrogen from a Kipp generator, by means of the interferometer, showed that it contained 83.86% H₂, after 17 mins., 93.59% after 22 mins., and 99.97% after 42 mins.—C. A. M.

Colour reactions of molybdenum. Barbieri. See XXIII.

PATENTS.

Concentrating solutions [sulphuric acid]; Method of —. H. V. Welch, Los Angeles, Cal., U.S.A. Eng. Pat. 134,593, 30.10.18. (Appl. 17,698/18.)

SEE U.S. Pat. 1,289,984 of 1918; this J., 1919, 163 A. Spray from dilute sulphuric acid is subjected to heat sufficient to evaporate it completely, and the vapour is then cooled to a temperature slightly below the maximum boiling point for sulphuric acid, to produce a mist of sulphuric acid of high concentration, which is precipitated electrically. The residual vapour is cooled to a lower temperature, at which practically the whole of the remaining sulphuric acid is condensed as a mist, which is also precipitated electrically to obtain sulphuric acid of lower concentration.

Sulphuric acid and other liquids; Apparatus for the fractional distillation of —. H. Jander, Brooklyn, N.Y. U.S. Pat. 1,321,210, 11.11.19. Appl., 8.3.19.

In a distilling apparatus, a duct for the passage of hot gases is arranged adjacent to, but out of communication with, the distilling chamber into which extend radiating devices adapted to absorb heat from the gases in the duct.—W. E. F. P.

Sulphuric acid; Process for obtaining free — from coal gas, Mond gas, etc. J. Behrens, Bremen. Ger. Pat. 300,036, 16.11.15.

THE ammonia-free gas is washed with water containing sulphurous acid. Sulphur is precipitated and thiosulphate and polythionic acids are formed. The latter are decomposed when the liquid is finally concentrated by the application of heat, yielding

sulphur dioxide, which is used again, sulphur, and sulphuric acid.—W. P.

Arsenious and selenious oxides [from pyrites]; Apparatus for the recovery of —. H. Jander, Brooklyn, N.Y. U.S. Pat. 1,321,211, 11.11.19. Appl., 3.4.19.

SEVERAL cells are arranged adjacent to a pyrites burner. Each cell is provided with cooling means and one is connected with a reheating device.

W. E. F. P.

Nitric acid of high concentration; Process for obtaining —. Farbenfabr. vorm. F. Bayer und Co., Leverkusen. Ger. Pat. 297,903, 30.5.15.

If steam and air are passed through a mixture of nitric and sulphuric acids containing nitrous gases, and the resulting nitrous vapours are dried by means of sulphuric acid, the yield of 95–96% nitric acid is almost quantitative. Any gases which pass out of the condenser are absorbed in sulphuric acid in a tower, and this acid then passes to the drying tower. Instead of pure sulphuric acid a mixture of sulphuric and nitric acids may be used as the drying agent. The amount of air and the dimensions of the condensing and drying apparatus depend on the amount of nitrous gases in the acid mixture. If there is much nitrous gas an oxidation chamber should be placed between the dryer and condenser.—A. B. S.

Hydrochloric and hydrobromic acids; Preparation of — from free chlorine or bromine. Consolidierte Alkaliwerke, Westeregeln. Ger. Pat. 313,875, 6.3.18.

CHLORINE or bromine is allowed to act upon lignite without external heating, the lignite being moved in the opposite direction to the gas stream. The temperature rises to 90°–100° C., at which the reaction proceeds. The product is extracted to remove halogenated products, and then treated to recover halogens by extraction or by distillation under reduced pressure. By the use of carbon bisulphide for extraction a by-product is obtained in the form of a halogen-containing resinous substance.—W. P.

Gases and vapours [nitric acid, hydrochloric acid, or the like]; Apparatus for condensing and purifying —. R. Rosenthal, Charlottenburg. Ger. Pat. 314,293, 21.7.18.

THE hot gases generated during the manufacture or distillation of nitric acid, hydrochloric acid, or the like, are passed upwards through a condensing tube, of which the lower portion is air-cooled and the upper portion is cooled by a stream of water. The gases are partially cooled in the lower portion and condensation is effected in the upper portion; the condensed liquid flows down the tube and meets the ascending stream of hot vapour whereby certain impurities, e.g., nitrogen peroxide in the case of nitric acid, are removed. The purified liquid passes out at the lower end of the tube, through a coil cooled by the overflow of cooling water from the upper portion of the condensing tube, and into a receiver; uncondensed gases leave the tube at the upper end and pass into an absorption apparatus.—L. A. C.

Magnesia; Process for the manufacture of — [from dolomite or the like]. J. C. Delage, Bordeaux, France. Eng. Pat. 134,626, 8.11.18. (Appl. 18,335/18.) Int. Conv., 8.11.17.

POWDERED dolomite, dolomitic limestone, or the like, is added gradually to a solution of sodium bisulphate heated to 80°–90° C. until the solution is neutral to litmus; calcium sulphate is separated from the solution by decantation, or by means of a filter press, and the precipitate is washed free from

soluble salts. Alternatively the powdered dolomite may be heated with dry sodium bisulphate at a temperature sufficient to fuse the latter, with subsequent extraction of the soluble salts by means of water. The solution of magnesium sodium sulphate obtained by either method is electrolysed by a current of $3\frac{1}{2}$ to 4 volts and 10 amps. per sq. dm. of anode surface in a vat separated into compartments by membranes impermeable by the solution but permeable by the current. The anode and cathode compartments are provided with carbon and sheet-iron electrodes respectively. The magnesite precipitated at the cathode is separated from the solution by filtration, and is washed and calcined. Free sulphuric acid is liberated at the anode, but as the precipitation of magnesite at the cathode decreases with increase of acidity, the liquor from the anode compartment overflows into a vessel in which it is neutralised by dolomite and is then returned to the apparatus.—L. A. C.

Magnesium carbonate; Process for obtaining —. A. T. Elliott, Assignor to A. L. Stewart, Los Angeles, Cal. U.S. Pat. 1,321,421, 11.11.19. Appl., 2.8.17.

MAGNESITE containing silica is leached with an acid liquor; undissolved matter and impurities are removed from the solution, and magnesium carbonate is precipitated by addition of a soluble carbonate. The precipitate is separated, and the solution is acidified and used for leaching a further quantity of magnesite.—L. A. C.

Magnesium hydroxide; Manufacture of pure —. O. F. Kaselitz, Bernburg. Ger. Pat. 313,943, 4.1.18.

MAGNESIUM chloride solution obtained in the manufacture of potassium chloride is mixed with the requisite amount of a solution of an alkaline-earth sulphide or hydrosulphide in the cold; any residue is removed, and the clear solution is boiled. If calcium sulphide is used, one-half of the magnesium is precipitated as magnesium hydroxide in accordance with the equations: $-2\text{CaS} + 2\text{MgCl}_2 + 2\text{H}_2\text{O} = \text{CaCl}_2 + \text{Ca}(\text{SH})_2 + \text{MgCl}_2 + \text{Mg}(\text{OH})_2$ or $= 2\text{CaCl}_2 + \text{Mg}(\text{SH})_2 + \text{Mg}(\text{OH})_2$, but if the calcium sulphide is converted to the hydrosulphide by passing hydrogen sulphide through the solution before addition of the magnesium chloride, or if hydrogen sulphide is passed into the cold mixed solutions, conversion of the magnesium chloride into magnesium hydroxide is practically complete.

—L. A. C.

Magnesium sulphate; Manufacture of —. E. E. and P. C. Dutt, Jubbulpore, India. Eng. Pat. 134,884, 18.10.18. (Appl. 17,076/18.)

A MIXTURE of calcium sulphide and a compound or mixture of compounds containing magnesium is subjected at a dull red heat in a reverberatory furnace to the action of air, steam, and of carbon dioxide when this is not formed during the reaction. Magnesium sulphate is obtained from the resulting mass by lixiviation.—S. S. A.

Potassium salts from blast furnace slag; Recovery of —. E. Bury, O. Ollander, T. Smith, and F. Bainbridge, Saltburn-by-the-Sea. Eng. Pat. 134,665, 3.12.18. (Appl. 20,009/18.)

CALCIUM chloride is added to a stream of molten blast-furnace slag as the latter is caused to flow down a cascade within a closed chamber. The vapour (potassium chloride) produced is drawn off and treated in scrubbers.—W. E. F. P.

Potassium sodium sulphate; Process of obtaining from saline liquors. G. B. Burnham, Borosolway, Cal. U.S. Pat. 1,321,282, 11.11.19. Appl., 16.6.19.

POTASSIUM sodium sulphate is precipitated by add-

ing sodium sulphate to liquor already containing suitable concentrations of potassium ions and sodium sulphate.—W. E. F. P.

Alkalis from silicates; Process of extracting —. R. C. Hills, Assignor to O. Newell, Denver, Colo. U.S. Pat. 1,321,632, 11.11.19. Appl., 5.12.18.

From a product containing calcium chloride and alkali chlorides obtained in the extraction of alkalis from silicates, the calcium chloride is dissolved out with alcohol.—S. S. A.

Ammonia; Removal of — from high-pressure gases. E. B. Maxted and T. A. Smith, Walsall. Eng. Pat. 134,572, 3.8.18. (Appl. 12,681/18.)

To remove ammonia from high-pressure gas mixtures, as obtained in the synthesis of ammonia from its elements, anhydrous cobaltous chloride at an elevated temperature is employed. The ammonia is absorbed when its concentration exceeds a certain partial pressure, and given up when this pressure is sufficiently diminished.—W. E. F. P.

Hydrogen-nitrogen mixtures; Process for obtaining —. Harburger Chemische Werke Schönn und Co., and W. Daitz, Harburg. Ger. Pat. 298,911, 18.5.15.

CARBON monoxide and dioxide are removed from water-gas by condensation or absorption; the carbon monoxide is employed for the quantitative combustion of oxygen in air or other mixture of oxygen and nitrogen, and the residual nitrogen is mixed with the mixture of nitrogen and hydrogen remaining from the water-gas for the preparation of nitrogen-hydrogen mixtures for the production of ammonia. The power required for the condensation or absorption under pressure is provided by the heat generated in the combustion of the oxygen.—A. B. S.

Ammonia; Manufacture of anhydrous —. A. Lowenstein, Chicago, Ill. U.S. Pat. 1,322,251, 18.11.19. Appl., 28.8.16.

A PORTION of the expanded gaseous ammonia resulting during the cyclic refrigeration process which involves the condensation, expansion, and re-absorption of ammonia obtained by heating an aqueous solution of the gas, is withdrawn and replaced by aqueous ammonia.—S. S. A.

Nitrogen fixation; Furnace for —. A. F. Crowell, jun., Saltville, Va., Assignor to Nitrogen Products Co., Providence, R.I. U.S. Pat. 1,321,892, 18.11.19. Appl., 7.3.18.

IN a vertical retort into which a charge is fed to react with free nitrogen, the walls are "offset" at the feeding point to prevent choking of the charge.—W. J. W.

Ammonia; Method of oxidising —. A. Classen, Aachen, Germany, Assignor to The Chemical Foundation, Inc. U.S. Pat. 1,322,291, 18.11.19. Appl., 24.1.16.

A MIXTURE of oxygen and ammonia is subjected to the action of catalysts formed from basic substances and substances capable of accelerating the oxidation of the ammonia, the basic substances being in excess of the active catalytic substances.—W. J. W.

Nitrogen; Process for oxidation of — in an arc with alternating current. Bergmann-Elektrizitäts-Werke A.-G., Berlin. Ger. Pat. 298,952, 7.1.16.

NITROGEN is oxidised in a chamber containing fixed electrodes, the supply of air passing through the chamber being varied synchronously with the periodicity of the alternating current used.

—A. B. S.

Cyanogen compounds; Process for the production of —. E. R. Lewis, Philadelphia, Pa. U.S. Pat. 1,321,459, 11.11.19. Appl., 15.3.19.

A CHARGE consisting of a powdered mixture of an alkali metal, carbon, iron, and an inert non-alkaline mineral is brought into contact with heated nitrogen in a heated reaction chamber. The proportions of the charge are such that there is sufficient carbon to combine with the alkali metal, sufficient iron to reduce the temperature of the reaction, and sufficient of the inert mineral to prevent the mass becoming viscid.—L. A. C.

Cyanides; Apparatus for producing — from nitrogen or air. H. B. Kipper, Muskegon, Mich. U.S. Pat. 1,322,026, 18.11.19. Appl., 19.2.18.

THE apparatus comprises a rotary reaction cylinder connected to a fuel furnace and a preheater, and regenerators each communicating at one end with the furnace and at the other end with the cylinder and the preheater.—S. S. A.

Aluminium chloride; Process for producing —. L. Burgess, New York, Assignor to Standard Oil Co. U.S. Pat. 1,321,281, 11.11.19. Appl., 3.1.19.

ANHYDROUS aluminium chloride is produced by bringing into contact, under reacting conditions, aluminium carbide and the chloride of an element below aluminium in the electrochemical scale as regards affinity for chlorine.—W. E. F. P.

Zinc oxide; Manufacture of —. Production of zinc oxide. Production of metal oxides and other metallic compounds. (A) and (D) F. G. Breyer, Palmerton, Pa., J. A. Singmaster, Bronxville, N.Y., and A. E. Hall, Palmerton, Pa.; (B) and (C) F. G. Breyer, A. E. Hall, and G. R. Waltz, Palmerton, Pa., Assignors to The New Jersey Zinc Co., New York. U.S. Pats. (A) 1,322,088, (B) 1,322,089, (C) 1,322,090, and (D) 1,322,091, 18.11.19. Appl. (A) 8.1.19., (B) and (C) 12.7.19. and (D) 1.8.19.

(A) IN the production of zinc oxide or lead-zinc oxide by the Wetherill process the bed fuel is supplied to the furnace hearth in the form of briquettes. The furnace hearth is supplied with a relatively deep layer of bed fuel in the form of briquettes, and on this ignited layer is spread a working charge of (B) zinciferous or zinciferous and plumbiferous or (C) other metalliferous material in admixture with a reducing agent. (D) IN the production of oxides or other compounds of volatilizable metals by the Wetherill process, the bed fuel is supplied to the furnace hearth in the form of briquettes.—S. S. A.

Metal oxides and other compounds of metals; Production of —. Manufacture of zinc oxide. J. A. Singmaster, New York, F. G. Breyer and E. H. Bunce, Palmerton, Pa., Assignors to The New Jersey Zinc Co., New York. U.S. Pats. (A) 1,322,143 and (B) 1,322,142, 18.11.19. Appl., 22.7.19.

(A) A BED of solid fuel is fed on to a moving perforated hearth, e.g., a chain grate, and passes under three compartments of the furnace. In the first the fuel burns with air admitted from below; in the second compartment a layer of a briquetted mixture of metal-bearing substance and reducing agent is fed upon the burning fuel, and in the third a combustion-supporting gas is supplied to the charge and the products of reaction are removed by any suitable means. (B) Zinc oxide or zinc-lead oxide is manufactured by the process described under (A).—B. M. V.

Tungstic acid; Recovery of — from ores. Imperial Trust for the Encouragement of Scientific and Industrial Research, and O. J. Stannard, London. Eng. Pat. 134,891, 6.11.18. (Appl. 18,206/18.)

FOR the recovery of tungstic acid from ores, residues, or other substances, e.g., wolframite, hübnerite, ferberite, and scheelite, the material is crushed, mixed with carbonaceous material, and heated to redness, the reduced mass being subsequently heated at about 300° C. in a current of chlorine gas, free, or almost free, from air. The volatilised or sublimed mass which results is treated with hot water, with or without the addition of nitric or hydrochloric acid. For the recovery of stannic chloride from wolfram ores the sublimate is heated with hot water and hydrochloric acid, and the resulting solution of stannic chloride is separated from the precipitated tungstic acid. The process may be made cyclic by heating the mixture of chlorides obtained in a current of dry air and using the chlorine thus recovered for the treatment of further quantities of ore.—S. S. A.

Arsenides of calcium or magnesium; Manufacture of —. J. D. Riedel A.-G., Berlin-Britz. Ger. Pat. 300,152, 18.4.16.

CALCIUM or magnesium is heated with arsenic together with some arsenide from a previous preparation as a diluent to slow down the reaction. Sand is used as the diluent in the first place. The products can be used for the preparation of other arsenic compounds.—W. P.

Alkali perchlorate; Method for the technical production of — by heating alkali chlorate. F. Meyer, Berlin. Ger. Pat. 300,713, 18.4.15.

IF the vessel containing the chlorate is heated in a metal bath so as to ensure accurate control of the temperature between 470° and 520° C. for potassium chlorate and 30° C. lower for the sodium salt, a yield of 70–75 parts of perchlorate for each 100 of chlorate is obtained. Below the temperatures mentioned the reaction is too slow; above them it is so rapid as to be dangerous. The reaction should be stopped when 80% of the chlorate has been converted, as its continuance after this point results in a lower yield.—A. B. S.

Lime mud; Process for treating — in rotary furnaces. G. Pelysius, Dessau. Ger. Pat. 313,595, 23.9.16.

WITH the lime mud is incorporated such materials as salts of the alkalis, potash mica, etc., which cause the lime to ball together and so not to pass out of the furnace in the form of dust, which would otherwise be carried forward to the chimney.

—H. J. H.

Ammonium bicarbonate; Preparation of a stable and odourless form of —. Oesterr. Verein für chemische und metallurgische Produktion, Aussig. Ger. Pat. 313,827, 22.12.17.

PRECIPITATED crystalline ammonium bicarbonate is carefully dried and then treated with moist carbon dioxide under pressure (2–3 atm.). In order to diminish its free surface the bicarbonate is briquetted before or after drying or before or after the treatment with carbon dioxide.—W. P.

Ammonium salts; Process for producing — from industrial gases containing ammonia. Chem. Fabr. Kalk Ges.m.b.H., Cöln-Kalk. Ger. Pat. 314,234, 8.5.15.

GASES containing ammonia are passed through a solution of iron. The gases must contain or have added to them sufficient carbon dioxide to ensure the complete precipitation of the iron as carbonate.

The liquid is filtered and the iron-free filtrate treated for the recovery of ammonium salts.

—A. B. S.

Hydrogen peroxide; Synthetic production of — and apparatus therefor. R. Moritz, Chatou, France. Eng. Pat. 120,045, 8.10.18. (Appl. 16,376/18.) Int. Conv., 15.5.17.

PALLADIUM or an alloy containing palladium in the form of a tube, ribbon, or wire, saturated with hydrogen is caused to act upon a solution of oxygen in water which may be under pressure. Means are provided for constantly renewing the supply of hydrogen—for instance, by moving the wire or band of palladium through an atmosphere of hydrogen in another vessel; or the hydrogen may be passed through the interior of a tube of palladium immersed in the liquid, which is maintained in the presence of oxygen under pressure. Alternatively, the process may be carried out by electrolysis in a vessel lined with ebonite, tin, rubber, or silver, and capable of resisting pressure, acidulated water saturated with oxygen being passed over the electrodes. The cathodes are composed of palladium or an alloy of palladium and the anodes of platinum, gold, graphitic carbon, or iron oxide fused in an electric furnace.—J. F. B.

Spathic iron ore; Means for treating — to render it suitable for use in the manufacture of hydrogen. W. J. and W. R. Bates, Silverdale, Staffs. Eng. Pat. 134,155, 13.3.19. (Appl. 6251/19.)

RAW ironstone is rendered highly porous by stacking it in a heap with a covering of small fuel, slowly burning the heap for a lengthy period, applying water to the hot mass when the ore is sufficiently calcined, and washing the cold material to remove fuel ash etc.—W. E. F. P.

Hydrogen generators. A. R. Griggs, London. Eng. Pats. (A) 134,901 and (u) 134,902, 9.11.18. (Appls. 18,382 and 18,384/18.)

HYDROGEN generators of the kind in which iron ore is alternately reduced and oxidised are usually made with an inner combustion chamber, a middle annular ore chamber, and an outer annular chamber surrounding the whole, the gases passing to a stack or hydrogen storage according to the operation being performed. (A) During the purging or change-over from reduction to oxidation primary steam is admitted to the base of the combustion chamber and passes through the whole apparatus, whilst secondary steam is admitted to the base of the outer chamber and sweeps that chamber and the stack outlet, so that the primary steam need only be sufficient to sweep out the combustion and ore chambers. A reduced pressure is maintained in the stack by means of steam jets, and all corners in the apparatus are rounded off as far as possible in order to facilitate removal of gases. (u) To aid the readjustment of the apparatus at the change-over, Venturi tubes with gauges are placed in the pipes for reducing gas and air supply, which indicate the pressure or volume (or both) of the gas or air passing.—B. M. V.

Carbon monoxide in hydrogen or gases containing the same; Apparatus for indicating and for recording quantities of —, applicable also for like purposes. E. K. Rideal, London, and H. S. Taylor, St. Helens. Eng. Pat. 134,243, 4.6.18. (Appl. 9205/18.)

By a process of catalytic fractional combustion in the presence of added air or oxygen, the carbon monoxide present in the gas under examination is converted into carbon dioxide, which is then brought into contact with lime water. Means are provided for recording the change in electrical con-

ductivity of the lime water and thus the amount of carbon dioxide absorbed. (See also this J., 1919, 807 A.)—W. E. F. P.

Graphites; Purification of natural —. E. Ridoni, Turin, and Soc. Talco e Grafiti Val Chisone, Pinerolo, Italy. Eng. Pat. 131,894, 8.11.18. (Appl. 18,330/18.)

PARTIAL separation of silica etc. from graphite is effected by the use of rather less than the theoretical quantity of hydrofluoric acid of lower concentration than that of the commercial concentrated acid, the advantages being that fume and waste of acid are avoided, wear of vessels is reduced, and the hydrofluoric acid may be prepared directly from sulphuric acid and a fluoride. Graphite containing 75–80 or even 80–85% C can be prepared in this way.—B. M. V.

VIII.—GLASS; CERAMICS.

Glass furnaces; Durability of the burners in —. H. Knoblauch, Sprechaal, 1919, 52, 407—III.

THE flames in the furnace should be as short as possible and the chimney only just tall enough to provide the requisite draught. There should be a

slight pressure in the furnace whereby gases pass outwards through any leaks in the brickwork. The distance between the bottom of the pots and the gas and air ducts should not be too great; 3 ft., though common, is excessive; 2 ft. 8 in. is ample, or the development of the greatest heat where it is not required will destroy that part of the furnace. The sides of the combustion chamber should be vertical or very slightly inclined; they should not be gathered inwards in a series of inverted steps, as is often the case, as this confines the heat too much to the combustion chamber. There should be at least two ports leading from each regenerator to the combustion chamber; too many ports are ineffective, as they cause the heat to remain in the combustion chamber. When the upper edges of the combustion chamber wear away too rapidly it is often a sign that the combustion of the gas is incomplete—possibly due to excessive draught. It may also be caused by carrying the walls of the gas and air ducts too far into the combustion chamber, and may be remedied by shortening them so that there is a distance of 16 in. between the top of these walls and that of the combustion chamber. The use of several midfeathers in the combustion chamber is undesirable; one is sometimes an advantage if placed between the two ports leading from the regenerator. To overcome the difficulties associated with a hot pocket for receiving any glass spilt in the furnace, the bottom of the combustion chamber may be inclined downwards to a door near the front of the furnace. On opening the latter any glass in the pocket may be removed without disturbing the action of the furnace. If the combustion chamber is divided by a movable midfeather and provided with two dampers—one for each half of the chamber—better control of the furnace is ensured.—A. B. S.

Lead oxide; Volatilisation of — from lead silicate [glass] melts. O. Anderson. J. Amer. Ceram. Soc., 1919, 2, 784—789.

EXPERIMENTS on the amount of PbO volatilised from the surface of lead silicate glasses at temperatures from 900° to 1400° C. showed that the rate of volatilisation from an unstirred glass heated for a short time (15 mins.) was almost identical with that from a stirred glass heated for a longer period (1 hour), but the rate of volatilisation in an unstirred glass rapidly diminished. The volatilisation of lead oxide in making optical glasses is too small to affect their refractive index if the conditions of heating are kept constant for all batches. Large losses on a commercial scale may be avoided by varying the rate of filling the pot and the use of covers.—A. B. S.

Calcined clays; Re-hydration of —. J. S. Laird and R. F. Geller. J. Amer. Ceram. Soc., 1919, 2, 828—832.

Raw clays, when heated in the presence of water in a high-pressure autoclave to 200°—250° C. for a very long time are not hydrated appreciably, but clays calcined at 600°—700° C. can be largely re-hydrated, and regain much of their former plasticity in 8—48 hours. After being worked up and dried two or three times, the re-hydrated material resembles a raw clay. Clays which have been calcined at higher temperatures are re-hydrated far more slowly and incompletely. The ease with which the re-hydration of lightly calcined clays occurs suggests that on ignition they form an anhydride which is broken down by other reactions at higher temperatures with the formation of sillimanite.—A. B. S.

Porcelain; Further studies of —. F. H. Riddle. J. Amer. Ceram. Soc., 1919, 2, 812—827.

THE effect of lime and magnesia on the micro-structure of porcelain is to reduce the temperature

at which the body matures, the finishing temperature of a body containing magnesia being lower than that of one containing lime. Solution of the quartz and the distribution and size of the sillimanite crystals vary according to the conditions of firing. The translucency of bodies containing lime and magnesia fired at cone 11 (1320° C.) is as great as that of a body containing only feldspar fired at cone 14 (1410° C.), as both lime and magnesia increase the sillimanite and the solution of the quartz, the latter being probably due to the decreased viscosity of the body. The addition of small amounts of dolomite to porcelains maturing between cones 9 and 11 (1280°—1320° C.) reduces the temperature of vitrification. It does not affect the colour. The toughness (as measured by the loss of weight of the material in a rattler test) is increased. An increase in the proportion of whiting reduces the toughness, but makes the mass more dense and vitreous. Bodies rich in dolomite are more crystalline and break with a coarse fracture; the solution of the quartz and the formation of sillimanite are well advanced. The compressive strength of porcelain containing 0—3% of whiting and dolomite averaged 51,228 lb. per sq. in., the greatest strength being obtained with whiting alone, but the difference is so small that dolomite may advantageously replace whiting, as it is cheaper and gives a greater resistance to chipping. On prolonged grinding the water of plasticity and the drying shrinkage are increased, but the working properties of the body are reduced. The effect is the same as an increase of fluxes or of ball clay. Fine grinding also causes earlier maturity and earlier overfiring.—A. B. S.

Porcelain; Relation between the composition and thermal expansivity of —. F. H. Riddle. J. Amer. Ceram. Soc., 1919, 2, 804—811.

PORCELAIN rods 2 cm. in diameter and of such a length that they were 31 cm. when fired to maturity were pressed in the stiff-plastic state in a small hydraulic press, and their coefficients of thermal expansion were determined for the temperature ranges 25°—200° C., 200°—400° C., and 25°—400° C. The first series of bodies contained 70—85% of clay, but never more than 50% of raw kaolin, the remainder being clay which had been calcined at cone 14 (1410° C.). The flint content was 0—18.5% and varied inversely with the feldspar. It was found that bodies high in clay showed low thermal expansion. The variations in the proportion of flint within the narrow limits possible in these bodies did not cause any decided reduction of expansivity. Bodies containing more than 64% of silica but less than 70% of clay showed a marked thermal expansion. In a second series in which flint was replaced by synthetic sillimanite the reduction in thermal expansion was much more marked than in bodies rich in clay, but a body with 85% of clay was not improved by the addition of sillimanite. The flint is the chief cause of thermal expansion, both on account of its inversion changes and also through the increase of the silica content of the body. The coefficient of expansion lies between the following limits:—First series: 25°—200° C., $2.9-6.1 \times 10^{-6}$; 200°—400° C., $3.0-5.3 \times 10^{-6}$; 25°—400° C., $3.1-5.5 \times 10^{-6}$. Second series: 25°—200° C., $3.1-6.2 \times 10^{-6}$; 200°—400° C., $3.5-5.1 \times 10^{-6}$; 25°—400° C., $3.3-5.5 \times 10^{-6}$. Bars of synthetic sillimanite burned to cone 26 (1580° C.): 25°—200° C., 2.7×10^{-6} ; 200°—400° C., 3.9×10^{-6} ; 25°—400° C., 3.3×10^{-6} .—A. B. S.

Silica bricks; Apparent versus true specific gravity of —. L. R. Office. J. Amer. Ceram. Soc., 1919, 2, 833—835.

A DRY chip of a brick, weighing about 10 grms., was boiled in water for 1 hour, and its sp. gr. determined by means of a Westphal balance. The

chip was afterwards ground to powder, dried at 100°C ., and the sp. gr. determined in a pyknometer. Of 27 samples tested in this manner, 22 showed a slightly higher, 2 the same, and 3 a lower true sp. gr., the mean true sp. gr. being 0.011 higher than the apparent sp. gr.—A. B. S.

Enamelling; Cause and control of blistering in sheet steel —. C. Treischel. J. Amer. Ceram. Soc., 1919, 2, 774—781.

A form of blistering in which the enamel splits off the steel sheet in an aggregation of small blisters or in parallel rows or striations is due to absorption of hydrogen liberated when the sheet is pickled in a 10% solution of hydrochloric acid. If the pickling process is replaced by treatment with a sand blast or if only a 3% solution of acid is used no blistering occurs. In the latter case the time required for pickling is not noticeably increased, but each piece should be brushed before washing so as to assist in the removal of the scale.—A. B. S.

Lead oxides. Andersen. See VII.

PATENTS.

Sheet-glass; Apparatus for the production of —. T. J. McCoy, Shinglehouse, Pa., U.S.A. Eng. Pat. 134,807, 11.10.18. (Appl. 21,788/19.)

AN apparatus for making sheet glass continuously consists of a tank for the molten glass, with an upwardly inclined bottom ending in an overflow-spout; an inclined cover for the spout, a movable front wall adjacent to the front end of the cover, and means for varying the inclination of the cover so as to create an air-space between it and the front wall and thus regulate the temperature of the glass. Guiding ribs extend over the top and front of the spout and hot air is passed through the space between the lower portion of the side walls and the spout so as to maintain the edges of the glass at the same temperature as the remainder. After the glass has flowed over the spout in a stream of regulated thickness it passes vertically downward and then along an annealing lehr.—A. B. S.

Sheet glass; Manufacture of —. J. Proeger, Pittsburgh, Pa. U.S. Pat. 1,320,091, 28.10.19. Appl., 9.8.18.

IN order to equalise the heat in glass sheets during the drawing operation the sheet is drawn through a substantially enclosed receptacle provided with a passage-way through it and with openings in the top and bottom. Gases enter the receptacle through the latter opening, and means are connected to the receptacle to draw the hot gases from the sides, thereby allowing the gases to move across the sheet.—B. N.

Glass ovens or furnaces. E. C. R. Marks, London. From Soc. Anon. Fours et Procédés Mathy, Liege, Belgium. Eng. Pat. 135,115, 14.1.19. (Appl. 9496/19.)

A GLASS pot-furnace comprises several chambers each containing a pot surrounded by fragments of porous refractory material, the bottom of each chamber being formed with cavities filled with such fragments and which receive air and gas at their base. A regenerator may be provided in the base of the furnace for heating the gas and air used therein. Heating is effected by flameless surface combustion.—A. B. S.

Hard porcelain for fuses; Process for production of —. Porzellanfabrik A. Schweig Ges.m.b.H., Weisswasser. Ger. Pat. 298,480, 22.12.16.

THE body mixture is mixed with oil and pressed into the desired shape. The oil ensures the ready removal of the mass from the dies, acts as a binder, and enables a dense and homogeneous porcelain to be produced.—A. B. S.

Glass. Corning Glass Works, Assignees of H. P. Gage and W. C. Taylor, Corning, N.Y., U.S.A. Eng. Pat. 127,586, 28.5.19. (Appl. 13,508/19.) Int. Conv., 28.5.18.

[Refractory] cement. U.S. Pat. 1,321,085. See IX.

IX.—BUILDING MATERIALS.

Lime-mortar. Dissolution and peptisation of solids. V. Kohlshütter and G. Walther. Z. Elektrochem., 1919, 25, 159—183.

AN experimental study of the hydration of lime in all its stages was undertaken in the hope of obtaining practical data in support of the authors' theory of the colloid state and the relation between colloidal and true solutions. The account of the experiments is preceded by a long theoretical discussion on the nature of solution, the hydration of lime, and the properties of mortar. The slaking of lime is a good example of the step-by-step character of the solution process, the stages being the formation of:—(a) calcium hydroxide; (n) hydrated forms of the hydroxide; (c) lime cream, a non-settling suspension or paste; (p) milk of lime, a colloidal suspension of lime in the saturated solution; (e) lime water, a true solution. It is emphasised that the structure of the material from which the lime is made must have a profound influence on the properties of the lime, on its slaking properties, on the character of the lime cream obtained, and on the hardening properties of the mortar, exactly as is found in practice. For the experiments lime was used prepared from calcium carbonate, hydroxide, and oxalate. When slaked by exposure in a damp atmosphere the three samples differed considerably in the rates at which they absorbed water. Up to the formation of the hydroxide the rates were nearly the same, but afterwards the lime from carbonate absorbed most and that from oxalate least rapidly. The former also absorbed the greatest total quantity, about 1.5 mols, and the latter the least, about 1.25 mols. When the products were dehydrated and again slaked in the same way, the influence of the original source was still manifest, showing that the specific structure of the particles had not been destroyed. The samples also showed marked differences in their rates of sedimentation when slaked with much water, and the rates and order of settling were found to depend on the method of slaking, i.e., whether the lime was added to water or the water poured over the lime. Different electrolytes present in the slaking water had different effects on the rates of sedimentation, some retarding and some accelerating the rate of settling. No definite conclusions could be drawn from the results of the experiments beyond the general inference that in the first stage of the action of water on lime complex chemical and capillary forces come into action with the colloidal particles of the solid. —E. H. R.

Cements rich in alumina. K. Endell. Zement, 1919, 8, 391—321, 331—336, 347—350. Chem. Zentr., 1919, 90, IV., 658.

THE ternary system, $\text{CaO}-\text{SiO}_2-\text{Al}_2\text{O}_3$, has been examined to determine the limits within which compounds capable of hydraulic setting are formed. It is shown that good cements are obtained from clinkers in which the following crystalline phases, which can be identified mineralogically, are predominant:— $\text{CaO}, \text{Al}_2\text{O}_3$; the group of calcium orthosilicates, $2\text{CaO}, \text{SiO}_2$; $3\text{CaO}, 5\text{Al}_2\text{O}_3$. The following do not form cements:— $3\text{CaO}, \text{Al}_2\text{O}_3$,

and gehlenite $2\text{CaO}, \text{Al}_2\text{O}_3, \text{SiO}_2$. The strength of the products under compression is dependent on the alumina content.—H. J. H.

Thermal conductivity of solid insulators. Thornten. See XI.

PATENTS.

Slabs [from leather waste]; Production of hard flooring or insulating —. H. Gronrose, Copenhagen. Eng. Pat. 124,415, 19.12.18. (Appl. 21,264/18.) Int. Conv., 19.3.18.

HARD flooring or insulating slabs are made by mixing 100 kilos. of pulverised leather waste with 3–5 kilos. of boiled linseed oil, drying the mass, mixing it with about 200 kilos. of spirit varnish, 1 kilo. of infusorial earth, and $\frac{1}{2}$ kilo. of red lead, and pressing into slabs under a pressure of 800 kilos. per sq. cm. Alternatively, the varnish and infusorial earth may be mixed with the leather, shaped under pressure, and the product coated with boiled linseed oil.—A. B. S.

Kilns; Apparatus for automatically discharging lime, cement, and like —. C. Candlet, Paris. Eng. Pat. 131,269, 12.11.18. (Appl. 18,542/18.) Int. Conv., 10.8.18. Addition to 119,235 (this J., 1919, 750 A).

THE lower part of a shaft kiln is provided with four cones, having horizontal axes and supported on separate shafts so as to leave a clear space adjacent to their apices, each cone being formed of two conical portions having different angles, with the apex directed toward the centre of the kiln. The smaller obtuse-angled portion near the apex may be provided with ridges or ribs to allow large pieces of material to pass between the cones without being subjected to heavy torsional stresses. The omission of central supports permits the admission of air to the centre of the kiln. Above the cones, and immediately below the grate through which the air enters, is a truncated cone or collecting ring, with a vertical axis, which directs the small pieces from the periphery to the centre of the kiln and relieves the pressure on the bases of the cones. The rotation of the collecting ring causes the cones to rotate by friction. In a modification, the cones are rotated mechanically so as to crush the material discharged from the kiln.—A. B. S.

Concrete. Harland and Wolff, Ltd., and A. Marks, Belfast. Eng. Pat. 134,598, 1.11.18. (Appl. 17,901/18.)

A LIGHT-WEIGHT concrete is made by mixing 2 parts by weight of Portland cement and 1 part by weight of sawdust, and damping the mixture by the addition of a fluid containing 1 vol. of sodium silicate to 3 vols. of water. Sufficient 10–20% solution of calcium chloride is then added to form a wet mortar containing a slight excess of sodium silicate. The surface of the concrete may be made waterproof by coating it with a similar mixture containing a smaller proportion of fine sawdust. If the surface is to be exposed to the weather it is also hardened by treating it with dilute hydrofluoric acid. Alternatively, hydrochloric acid may be used instead of calcium chloride solution if the cement contains sufficient free lime, or if lime is added as a filler.—A. B. S.

Concrete; Pumice aggregate for —. A. Ham-bloch, Andernach. Ger. Pat. 310,120, 14.8.18.

PUMICE powder is freed from coarse particles by levigation and then dried and used as an aggregate with or without previously coating it with cement slurry, milk of lime, etc., in order to make it impervious externally. Such pumice only weighs 200–250 kilos. per cb.m.—A. B. S.

[Refractory] cement. H. B. Boeth, Assignor to A. Ramsay and Son Co., Montreal, Canada. U.S. Pat. 1,321,085, 11.11.19. Appl., 18.11.18.

A PROTECTIVE coating for bodies subjected to high temperatures consists of a mixture of felspar, angular grains of crushed quartz, silica sand, and a binder.—A. B. S.

Roofing, flooring, or paving materials; Manufacture of —. W. Bunte, Hannover-Linden, and W. North, Hannover. Ger. Pat. 313,565, 8.11.18.

NATURAL or artificial hollow particles are mixed with ground pitch and compressed. The product obtained by mixing pitch with ground calcined kieselsguhr has a rich copper colour. It is resistant to wet, frost, and sunshine, and particularly towards changes of temperature. It can be used either as flooring or roofing material.—H. J. H.

Asbestos cement sheets; Process for glazing —. A. Silber, Offenburg. Ger. Pats. (A) 313,594, 9.4.16, and (B) 313,939, 9.9.16.

(A) THE sheets are fired, allowed to cool to 70° – 100° C., and dipped for a short time into a soap solution at the same temperature. The soap reacts with the quicklime, forming an insoluble lime soap, which fills up the pores left by the dehydration under heat so that the material regains its original strength. (B) The articles, after coating with the glazing material, are heated under load or tension, to the temperature of incipient melting of the glaze, after which the load is removed and the melting completed. A uniform and unbroken glaze surface is produced and distortion of the body is avoided. After the burning the article is treated with a soap solution as in (A).—H. J. H.

Fireproofing. U.S. Pat. 1,321,708. See V.

Preserving wood. Ger. Pat. 299,761. See V.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Open-hearth furnaces; Improvements in the technique of furnace firing, with special reference to —. W. Tafel. Stahl u. Eisen, 1919, 39, 1280–1283.

FROM the nature of the firing of most metallurgical furnaces the greater part of the heat supplied is lost in the waste gases. In order to utilise this waste heat, three courses may be adopted—preheating the material treated, preheating the gas and air for combustion, and the application of special heating installations, as, for example, steam boilers. For reclaiming the waste heat from hearth-melting furnaces the first method is not practicable and the second only partially. The installation of steam boilers in connection with open-hearth furnaces introduces some difficulties, especially the danger of explosions. This danger may be partially overcome, but not completely, by reversing the gas and air at different times. In order to make explosions impossible it is recommended that the waste gases coming from the gas and air regenerators be drawn through separate channels after passing the reversing valves.

—T. H. Bu.

Steel; Viscosity of — at high temperatures. P. Chevenard. Comptes rend., 1919, 169, 712–715.

THE increase in length of a wire maintained at constant temperature and subjected to a weight applied without shock was recorded on a photographic plate having a uniform transverse motion, so that a curve representing extension : time was plotted. Oxidation was prevented by heating the wire in an atmosphere of nitrogen, and for each metal a series of heatings was made varying the initial condition of the wire, the temperature, and the load. Using a self-hardening nickel-chromium

steel, the curve approximates to a straight line with a constant rate of extension (V) for any particular temperature, though this factor is altered if the diameter of the wire is reduced appreciably. Regarding the rate of extension (V) as a coefficient indicating the degree of viscosity, and plotting it with varying load against temperature, the curve mounts very steeply at a temperature of 500° – 600° C., indicating the elimination of internal stresses as soon as a red heat is attained. The increase in extension, rdt , in the time dt is equal to the decrease in elasticity $\left(\frac{dp}{E}\right)$, resulting from the reduction in section (dp), so that $rdt - dp/E = 0$. The solution of this equation is the time $\left(t \frac{p_1}{p_0}\right)$ of heating capable of bringing the original tension, p_0 , to a given value, p_1 , and, accepting certain assumptions, a value is obtained,

$$t \frac{p_1}{p_0} = \frac{1}{E} \int_{p_0}^{p_1} \frac{dp}{V}$$

It is deduced that for all steels with the exception of high-speed steels, the usual practice of annealing for several hours at 600° – 700° C., followed by slow cooling, is sufficient for the removal of internal stresses caused by heat treatment or mechanical working.—C. A. K.

Molybdenum in steel and iron; Qualitative and quantitative test for —. S. L. Malowan. *Z. anorg. Chem.*, 1919, 108, 73–80.

A SPECIFIC and very sensitive test for molybdenum is given by xanthic acid. The test is best carried out with freshly prepared xanthate solution in the following manner: A solution of potassium hydroxide in absolute alcohol is shaken with excess of carbon bisulphide until no more of the latter is dissolved. To the solution so obtained 30% acetic acid is added until a slight yellow turbidity is formed, and the reagent is added drop by drop to the solution to be tested. If the latter has been prepared by dissolving the test material in strong acid, most of this should be neutralised before adding the reagent. If molybdenum is present an intense red colour immediately develops, which is quite stable in water and the intensity of which is proportional to the amount of molybdenum present. The sensitiveness of the reaction is such that 0.000005 grm. Mo in 0.0007% solution can be detected with certainty in presence of other elements. The colour is readily soluble in alcohol, amyl alcohol, ether, and chloroform, less readily in petroleum spirit and benzene. It is readily extracted from its reddish-violet ethereal solution by alkalis, and is precipitated from the alkaline solution by acids. The ethereal solution decomposes on standing with formation of molybdenum sulphide. The reaction is not given by vanadium, tungsten, titanium, or uranium; chromates give a dark coloration with xanthic acid, and should be reduced, if present, before the test is made. The reaction can be used for the colorimetric estimation of molybdenum, by comparison with a standard solution, but since ethereal solutions decompose too quickly, the ether should be mixed with 35% of petroleum spirit for the extraction and with 70% of petroleum spirit for the necessary dilution.

E. H. R.

Heuser's [magnetic] alloys. O. von Auwers. *Z. anorg. Chem.*, 1919, 108, 49–69.

A THEORETICAL discussion of the ferromagnetic alloys of the aluminium-manganese bronze series. Their properties are explained on the assumption that the magnetic carriers are of the form $(AlM_3)_x$, where M_3 is an isomorphous mixture of manganese and copper. These complexes dissociate at the magnetic transition temperature, about 600° C. When the alloy is quenched from this temperature

it has very weak magnetic properties, because there is no opportunity for the complexes to re-form. By slow cooling or by the so-called ageing process, i.e., prolonged heating at temperatures between 100° and 300° C., the molecules become associated to form the magnetic particles, and the magnetic properties of the alloy are developed. The theory explains the rise of the magnetic transition temperature as the time of ageing is lengthened, and also the rise in the value of the coercive force as the ageing temperature is raised to about 260° C. and the subsequent fall in its value when higher temperatures are used. (See also *J. Chem. Soc., Jan., 1920.*)—E. H. R.

Manganese-bismuth, manganese-zinc, and manganese-silver alloys. P. Siebe. *Z. anorg. Chem.*, 1919, 108, 161–183.

MANGANESE and bismuth are not completely miscible, but show a gap between 23% and 99.5% Mn. By the cooling curve method five arrest points were found, at 259° , 442° , 597° , 1043° , and 1252° C. The first and last represent the separation of eutectics containing respectively about 0.5% Mn and 0.5% Bi, whilst the others indicate three compounds, the compositions of which have not been determined. The five phases can all be distinguished microscopically. The first compound separates from alloys containing from 0.5 to 9% Mn, the second from those with 9 to 11% , and the third from those with 11 to 20% Mn. Mixtures containing more than 23% Mn separate into two layers. The hardness increases with the manganese content. The alloys are ferromagnetic, this property being peculiar to the first of the above compounds. Zinc-manganese alloys were prepared containing up to 50% Mn. A zinc-mixed crystal eutectic was found at 416° C., containing a very small proportion of manganese. The mixed crystals may contain from 11% to 50% Mn. Alloys containing only 2% Mn are hard and brittle; the hardness increases with the manganese content and with 40% Mn the hardness is 5 on Mohs' scale. Silver-manganese alloys show a sharp change in chemical and electrical properties at about 14.5% Mn (0.25 mol.). Those containing less than this proportion of manganese are unattacked by solutions of silver and copper salts or by dilute acids, whilst those with more than the limiting amount of manganese are rapidly attacked. (See also *J. Chem. Soc., Jan., 1920.*)—E. H. R.

Flotation; A contribution to the study of —. H. L. Sulman. *Inst. Min. and Met.*, Nov. 20, 1919. [Advance copy.] 95 pages.

THE author explains the complex of facts associated with flotation on the broad lines of the molecular hypothesis. Flotation reactions arise from the unbalanced molecular attractions in the surface layers of solids and liquids which are the seats of excess energy. Selective wetting effects always occur in the direction of the greatest possible reduction of interfacial energy. High interfacial energy implies low liquid/solid adhesion and floatability, and *vice versa*. Degree of wetting is connected quantitatively with the contact angle. For pronounced floatability this should approach or, preferably, exceed 90° . For complete wetting the interfacial tension must be nil, a condition which coincides with complete deflocculation. The hysteresis of contact angles permits a wide range of equilibrium for a floating particle. The addition of reagents to pure water and crushed ore and specific procedures are necessary to intensify preferential wetting effects until they become of practical use in the separation of sulphide minerals from gangue. An immiscible oil is employed to diminish the surface energy of the sulphide, and the addition of acid or alkali to the water promotes adhesion between gangue and water. Solid surfaces are probably penetrated by the molecules of liquids, and their

adhesion thus enhanced. Solid surfaces undergo molecular modification by friction, and molecules of any liquid in contact with them are included in greater number in the modified surface. This is of importance in the wet crushing of ores. Freshly-broken solid surfaces often undergo a spontaneous molecular alteration with a diminution of surface energy. Concentration of foreign molecules at the surface of a pure or homogeneous liquid reduces the surface tension and confers the property of frothing. Frothing reagents leave a partial strain at the bubble surface; mineral adsorption stabilises the film, especially if the mineral be oiled or flocculated. The bubble system should be disseminated through the ore pulp mass. By the use of acid, alkalis, sodium silicate, and certain sols deflocculation results by removal of strain from the surfaces of suspended particles. Particles tend to agglomerate by the coalescence of their strained layers. Flocculation is increased by mechanical agitation, minute oiling of the particles, and by contact with air (bubbles). In standard mineralised froths the layers may be scores of particles in thickness. If a substance can be flocculated it can generally be floated. Electrical phenomena are of minor importance. Flotation depends on bringing about the most advantageous selective adhesions, selective adsorptions, and selective flocculations between the ore pulp particles. α -Naphthol and xylydine mixture as a flotation agent. Chem. and Met. Eng., 1919, 21, 418.

ACCORDING to the Annual Report of the Consolidated Coppermines Co., by the introduction, in place of a mixture of coal tar, coal-tar creosote, and pine oil, of a mixture of α -naphthol and xylydine as flotation agent in an alkaline circuit, the concentrating ratio has been increased from 14'68:1 to 17'0:1, and the moisture content of the filter-cake reduced from 17'5 to 9'39%. The increased cost of reagents is more than compensated by a decrease of more than half in the freight and smelter charges, and by a threefold increase in the capacity of the filter-presses. From a mill-head material containing 1'4% Cu a concentrate containing 18% Cu can be produced, and the iron, sulphur, and insoluble content may be governed within such limits as to permit of smelting the concentrate with less than 20% of barren flux.

Colloidal copper. Gutbier and Sauer. See XX.

PATENTS.

Iron and steel; Process for the manufacture of —. D. R. Blair and H. B. Clapp, London. Eng. Pat. 134,283, 26.10.18. (Appl. 17,509/18.)

FINELY-DIVIDED iron ore is heated to about 1350° C. with a carboniferous reducing agent, together with sodium chloride and other materials, so as to produce a fusible slag which will readily flow away from the reduced metallic iron, leaving the latter unmelted and in a spongy condition. It is claimed that ores high in phosphorus, sulphur, or titanium will yield a more pure iron by this method owing to the reduction taking place without fusion of the metal. The spongy mass may be squeezed and forged into wrought iron, or converted into steel.

—C. A. K.

Steel and steel articles; Surface hardening of —. Vickers, Ltd., London, and W. J. D. Sherwood, Sheffield. Eng. Pat. 134,599, 1.11.18. (Appl. 17,903/18.)

A MODIFICATION for special purposes of Eng. Pat.

5588 of 1910. Air-hardening steel (*e.g.*, for tools) at a temperature (650°—800° C.) below the hardening temperature is subjected to rapid heating to above the hardening temperature and subsequently cooled. The time of heating is not sufficient to allow the interior of the metal to become heated by conduction above the temperature at which hardening takes place. Heating may be effected by passing an oxyacetylene flame over the surface at a speed of from 4 in. to 10 in. per min. according to the particular steel treated.—C. A. K.

High-speed steel. J. R. Valentine, Fulton, N.Y. U.S. Pat. 1,321,163, 11.11.19. Appl., 27.2.18.

A STEEL containing 13—14% W, about 5% Cr, about 1% V, less than 1% C, and 1%—1'25% Mn.

—J. W. D.

Steel; High-speed — containing chrome, tungsten, and molybdenum with addition of cobalt. Oberschlesische Eisen-Industrie A.-G., Gleiwitz. Ger. Pat. 300,765, 19.2.16.

IN a steel with almost 7% of tungsten, cobalt and molybdenum amounting to 5—10% together are used in place of any further tungsten required. In such a steel a molybdenum content of 2—6% and cobalt content of 5—2% may be used provided that the sum of the two does not exceed 10%. A satisfactory product contains C 0'65%, W 5'5%, Mo 3'2%, Co 3'5%, Cr 4'8%, V 0'4%. If the molybdenum content exceeds 6% the steel becomes more difficult to work, sensitive to heat, and brittle.

—H. J. H.

Steel; Manufacture of —. A. H. Henderson, Baltimore, Md. U.S. Pat. 1,322,496, 18.11.19. Appl., 18.2.19.

IN the production of steel for ingots or castings, chloride of lime (15 lb.), anhydrous aluminium oxide (2 lb.), and anhydrous borax (2 lb. per ton of metal) are added during the fusion of the charge; and lead (6 lb.) and zinc (1—2 lb. per ton of metal) are added to the molten metal in the ladle.

—W. E. F. P.

Steel; Process for making basic — by a combined open-hearth and converter process. O. Thiel, Landstuhl. Ger. Pat. 290,632, 24.2.15.

A PART of the Thomas charge is refined in the open-hearth furnace, and is then added to the converter charge and the whole blown together, or after blowing the converter charge, the refined metal from the open-hearth furnace is added, and the refining completed by further blowing. The refined metal, which is poured into the mixer for raising the temperature of the pig iron, must not be made from Thomas pig iron. It may be made by melting scrap and other pig iron together. The mixer iron should contain enough phosphorus for carrying out the Thomas process. Besides other advantages the time of blowing in the converter is reduced.—T. H. Bu.

Cast iron; Production of refined — from ordinary pig iron. Vereinigte Hüttenwerke Burbach-Eich-Düdelingen, Werk Dommeldingen, Luxemburg. Ger. Pat. 306,482, 27.6.16.

THE iron is refined in a reverberatory furnace under such conditions that, as far as possible, removal of the carbon avoided. High-phosphorus iron, as required for chill cast rolls, with up to 0'4% of phosphorus, is made by arresting the process at the correct moment. A highly-basic slag is used. Silicon is removed first, and if the quantity is large the silicious slag is poured off, whereupon dephosphorisation proceeds more rapidly. Sulphur and manganese are removed with the phosphorus. When dephosphorisation has proceeded sufficiently far, the slag is poured off, lime added, and about half the charge is poured and alloyed with ferro-

silicon and ferromanganese. To the other half in the furnace a fresh charge of pig iron is added.—H. J. H.

Furnace, especially for manufacture of iron and steel. W. Corsalli, Berlin, Ger. Pat. 313,620, 19.9.13.

THE furnace is equipped with regenerators for gas, air, or both, and a chamber traversed by the waste gases in which slag can be kept molten. The hot waste gases pass downwards from the hearth and through the slag chamber and then to the regenerators. Additional burners are provided in the slag chamber whereby its temperature can be further raised if necessary. By arranging that the flame passes in one direction only, it is possible so to construct the furnace that the gas stream passes between an inner and an outer stream of air or vice versa. Thus the flame has two zones of combustion—an inner and an outer—which facilitates control of its position and oxidising or reducing character by regulation of the pressure of air and gas. To avoid excessive heating of the furnace wall opposite the burner, as a result of the unidirectional character of the flame, this wall is set back so as to leave room for a chamber where preheating of charges and crucibles can be effected. Additions can be made to the slag while in its melting chamber so as to increase its value as a fertiliser or as a paving material. The slag may also be removed from the furnace and granulated preparatory to the recovery of titanium.—H. J. H.

Heating steel ingots; Furnace and process for —. K. Koller, Buda-Pesth, Ger. Pat. 313,757, 10.1.18.

THE furnace is designed to enable the ingots while remaining stationary to be heated to various temperatures and at various speeds simultaneously. Thus the ingots for the production of Mannesmann tubes can be rapidly heated to redness, then maintained at a temperature to relieve internal strains, and subsequently heated to the temperature of rolling. The heating gas is introduced by jets at the top of the furnace, and the air through ports running along the side at the floor level. The furnace is divided into sections each capable of independent regulation of temperature, either by division walls and independently regulated gas and air ports or by long, narrow air ports in the floor capable of independent control by valves.—H. J. H.

Iron or steel; Treatment of — for prevention of oxidation or rusting. L. S. Chadwick, East Cleveland, and M. Resek, Cleveland Height, Assignors to Cleveland Metal Products Co., Cleveland, Ohio. U.S. Pat. 1,320,734, 4.11.19. Appl., 6.2.17.

THE metal is treated with a solution containing an alkali phosphate, a salt of a metal less basic than iron, and an acid.—A. E. D.

Rustless surface on iron and steel; Production of a — by boiling phosphoric acid. W. Schmidting, Cöln-Mannsfeld, Ger. Pat. 313,578, 1.5.18.

AN anti-rust solution containing phosphoric acid, calcium, and zinc is mixed with metallic oxides and water. When applied to the iron articles a layer of intimately mixed zinc-iron phosphates is produced on the surface. The calcium phosphate, in an extremely fine state of division, is distributed through the coating, making it more resistant and adhesive.—H. J. H.

Electric furnace for heating, annealing, or melting metallic materials. Stabilimenti "Biak" Ing. A. Pouchain, Turin, Italy. Eng. Pat. 124,438, 10.3.19. (Appl. 5931/19.) Int. Conv., 9.3.18.

A FURNACE is built up of a number of elements of annular form, made of magnetic material. Longi-

tudinal insulated conducting bars of high ohmic resistance pass through holes in the elements parallel to the axis of the furnace, and are connected so as to form one or more complete turns. When an alternating current is passed through the conductor, the heating effect is due partly to resistance and partly to induction effects. The separate elements may be spaced by insulating air gaps or by layers of refractory material in order to modify the power factor of the furnace.—C. A. K.

Electric resistor; Zig-zag carbon —. Electric furnace for reducing oxidised zinc concentrates by carbon. J. Thomson, New York. U.S. Pats. (A) 1,321,682 and (B) 1,321,683, 11.11.19. Appl., (A) 7.10.18, (B) 27.1.19.

(A) Two contiguous zig-zag carbon resistors, connected with each other at one end and separated by a narrow slot. (B) A furnace for the reduction of zinc concentrates is heated by a carbon resistor of the above type, the surface of which is relatively non-conducting and immune from oxidation. The resistor is surrounded by the charge to be reduced, and is non-reactive with the reducing agent (carbon) in the centre of the furnace.—C. A. K.

Blast furnaces; Process for reduction and smelting in —. A. Torkar, Vienna. Ger. Pat. 313,619, 3.1.18. Int. Conv., 13.12.17.

REDUCING gases are introduced at the top, and in their passage downwards through the charge reduce the ore to the metallic state and bring the whole to fusion by combustion with preheated air supplied at the tuyères. The products of combustion pass through openings in the wall of the crucible and away into flues at the ground level.—H. J. H.

Converter. A. Nielsen and A. Birkedal. Ger. Pat. 313,756, 11.10.17.

A CONVERTER for melting metal by means of gas or sprayed fluid fuel, and subsequent purification by blowing air through the molten metal, is provided at one side with a container for the pig iron, which melts down into the working space of the vessel, the throat being closed with a cover. The products of combustion are led out through a flue leading from the working space of the converter to the container for the pig iron. The air pipe is provided with a reversing switch, so that the air can be passed to the burners or to the tuyères as desired.—T. H. Bu.

Siemens-Martin furnace, with built-in gas producer. P. Ostendorf, Vienna. Ger. Pat. 313,781, 20.4.18.

THE gas producer communicates directly with the hearth by slit-shaped ports, through which the gas enters. The sensible heat of the producer gas is therefore made effective in attaining a high temperature in the hearth. The air heated in regenerators is introduced above the gas ports and under such pressure as to drive the flame down upon the bath.—H. J. H.

Aluminium or aluminium alloys; Method of tin-soldering and tin-coating —. A. G. Bloxam, London. From Stabilimenti "Biak" Ing. A. Pouchain, Turin, Italy. Eng. Pat. 131,315, 30.10.18. (Appl. 17,739/18.)

A COATING of iron is deposited electrolytically on aluminium or an alloy of aluminium, the electrolyte consisting of a mixture of equal parts of a 4% solution of ammonium oxalate and a 2% solution of ferric sulphate. A current density of about 0.15 ampère per sq. dm. of cathode is used. The surface may then be tin-soldered or coated, using an acid solution of zinc chloride as cleaning agent.

—C. A. K.

Solder for aluminium. J. G. Kelly, Assignor to H. Hall, Sedalia, Mo. U.S. Pat. 1,321,529, 11.12.19. Appl., 10.2.19.

Zinc, lead, block tin, and a flux-like ingredient containing stearic acid are mixed in equal proportions and heated together with a small amount of skunk oil.—J. W. D.

Metal alloy. J. A. Weiger, Union Hill, N.J., Assignor to The Independent Lamp and Wire Co., Weehawken, N.J. U.S. Pat. 1,321,170, 11.11.19. Appl., 25.8.19.

An alloy containing 77—80% Ag, 18—20% Cu, and 2—3% Pt.—J. W. D.

Alloy. F. M. Becket, Assignor to Electro-Metallurgical Co., Niagara Falls, N.Y. U.S. Pat. 1,322,158, 18.11.19. Appl., 7.6.18.

An alloy of magnesium, silicon, and manganese, containing magnesium in excess of the equimolecular proportion to the silicon.—W. E. F. P.

Lead-tungsten alloys; Manufacture of —. H. Falkenberg, Weetzen. Ger. Pat. 299,052, 23.5.14.

A LITTLE finely-divided iron is added to a mixture of lead and tungsten before heating the same to form an alloy. By this means homogeneous alloys may be prepared containing lead and tungsten in any proportion.—L. A. C.

Tin or antimony; Alloy suitable as substitute for —. W. Zimmer, Giessen. Ger. Pat. 306,382, 21.10.17.

An alloy of arsenic and cadmium in approximately equal proportions may be used as a substitute for tin or antimony in the manufacture of alloys of the same with lead or copper, such as hard lead, bearing metal, type metal, etc.—L. A. C.

Alloy. G. Fuchs and A. Kopietz, Berlin. Ger. Pat. 310,041, 24.1.18. Addition to Ger. Pat. 307,764 (this J., 1919, 910 A).

THE tungsten content of the alloy specified in the chief patent may be increased to about 60%. The alloy may consist, for example, of W 57%, Fe 33%, Ti 5%, C 3%, and Ce 2%.—T. H. Bu.

Defects in metallic articles; Method of developing —. F. G. Brettell, Birmingham. From The Sneed and Co. Iron Works, Jersey City, N.J., U.S.A. Eng. Pat. 134,791, 5.7.19. (Appl. 16,850/19.)

METALLIC articles, such as tubes, are placed between electrical contacts and a current of low voltage and high amperage is passed so as to heat the tubes to the decalescence point. Seams, segregations, or other defects, which produce increased resistance to the passage of the current are indicated by overheating of the particular portion of the tube. This method of heating may be used at the same time for heat treatment of the article, which may be examined visually, after cooling, for overheating effects.—C. A. K.

Compressing powdered tungsten, tantolum, and the like; Means and method of —. C. A. Pfanstiehl, Highland Park, Ill., Assignor to Pfanstiehl Co., Chicago, Ill. U.S. Pat. 1,321,125, 11.11.19. Appl., 24.10.16.

POWDERED refractory metals are pressed into irregularly formed articles by placing the powder between a metallic cup and a die and subjecting the interior of the cup to fluid pressure, whereby the cup is expanded to compress the powder between it and the die.—J. W. D.

Metals of high melting point [tungsten, molybdenum, etc.]; Manufacture of articles from —. L. Reimann, Berlin. Ger. Pat. 302,650, 8.8.14.

IN the manufacture of articles from tungsten,

molybdenum, or the like, by compression and subsequent heating, a portion of the article is formed from a mixture of the powdered metal with a small percentage of another metal of melting point higher than that of copper, e.g., nickel, cobalt, or platinum; subsequent heating causes this portion of the article to contract and bind itself firmly to another part of the article. An anticathode, for example, may have a face of pure tungsten with a backing of tungsten containing a small quantity of platinum. A rod fitting tightly in a hole bored in the backing becomes permanently fixed when the backing contracts on heating. A suitable powder may be prepared by heating tungsten oxide moistened with a solution of a suitable salt at 1000°—1200° C. in a current of hydrogen.—L. A. C.

Pickling bath. W. H. Allen, Detroit, Mich. U.S. Pat. 1,321,182, 11.11.19. Appl., 10.5.17.

SURFACES of iron and steel having patches of oxides of iron are cleaned by immersing in a bath wherein the oxides will be reduced by sulphurous acid and the reduced metal dissolved by sulphuric acid. The articles are then removed and treated to prevent rusting.—J. W. D.

Metals of low melting points and different specific gravities; Apparatus for separating mixtures of —. F. Hoffmann, Berndorf, Austria. Ger. Pat. 299,724, 2.7.19. Int. Conv., 23.6.16.

A VESSEL for containing the alloy of metals of low melting point to be separated into its constituents, e.g., an alloy of lead with tin or zinc, a delivery pipe with regulating valve, and a centrifugal separator similar to a hydro-extractor are contained in a heating chamber. A current of a pre-heated reducing gas containing little carbon dioxide, such as producer-gas, water-gas, power-gas, or hydrogen, is passed through the chamber, and to ensure uniform heating the gas is led in from all sides through a number of adjustable openings. On leaving the chamber the gas is mixed with air and burnt, and the heat produced is utilised to heat the fresh supplies of gas.—L. A. C.

Metallic coatings on the inner walls of tubes, etc., of small diameter; Process for depositing —. R. Mylo, Charlottenburg. Ger. Pat. 312,409, 27.11.17.

THE wire anode is stretched between two vessels of insulating material attached to the ends of the pipe or channel to be coated, which vessels serve also for the admission and discharge of the electrolyte. The tautness of the anode may be regulated by an electro-magnet. The anode and the walls of the channel to be coated may move relatively to each other, either in the longitudinal direction or about the axis or in both directions. The arrangement is described in connection with the copper plating of the interior of a channel extending longitudinally through an arc-light electrode, a copper wire being used as anode.—J. F. B.

Electric arc welding and repairing. C. J. Holslag, South Orange, N.J., U.S.A. Eng. Pat. 128,186, 21.11.18. (Appl. 19,147/18.) Int. Conv., 11.6.18.

Coating sheet metal with tin or other metal [on one side only]; Machine for —. J. Powanda, Ansonia, Conn., U.S.A. Eng. Pat. 135,327, 4.12.18. (Appl. 20,076/18.)

Manganese steel; Method of recovering —. E. C. R. Marks, London. From American Manganese Steel Co., Chicago, Ill., U.S.A. Eng. Pat. 134,917, 12.11.18. (Appl. 18,525/18.)

XI.—ELECTRO-CHEMISTRY.

Mercury; Preparation of colloidal — by cathodic disintegration. A. Gutbier and G. L. Weise. Kolloid-Zeits., 1919, 25, 97—100.

MERCURY sols may be prepared by striking an arc between a clean mercury surface and a thin platinum foil cathode under water or a solution of a protecting colloid such as gum arabic. The sols are grey in colour and not very stable. They coagulate irreversibly on the addition of very small quantities of electrolytes. (See also J. Chem. Soc., Jan., 1920.)—J. F. S.

Colloids; Synthesis of — by means of oscillating arcs. G. Börjeson and T. Svedberg. Kolloid-Zeits., 1919, 25, 151—158.

FAIRLY stable colloidal solutions of antimony, lead, bismuth, zinc, gold, platinum, silver, copper,

aluminium, and cadmium are prepared by burning an oscillating arc under alcohol. Using a capacity 12.8×10^{-2} MF and a current of 1.5 amps. at 400 volts the colloidal solutions are produced rapidly.

—J. F. S.

Electrical endosmosis of molten sodium chloride into carbon. Wa. Ostwald. Kolloid-Zeits., 1919, 25, 115—116.

WHEN molten sodium chloride is electrolysed between carbon electrodes there is scarcely any evolution of chlorine or formation of sodium unless special conditions are established, but the negative electrode increases in bulk and is partially destroyed. On cooling and treating with water the electrode falls to powder, whereas the positive electrode is unaffected either during electrolysis or on treatment with water. This behaviour is due to the cataphoresis of molten sodium chloride.—J. F. S.

Luminous phenomena observed in the neighbourhood of a plate of graphite raised to a high temperature by means of an electric current. G. A. Hemsalech. Comptes rend., 1919, 169, 915—918.

WHEN a sufficiently powerful current is passed through a graphite plate held in a horizontal position and having its upper surface covered with carborundum powder, certain luminous phenomena are observed. When the plate is incandescent yellow vapours appear from the carborundum, and as the temperature rises these turn bluish, become luminous, and give a continuous spectrum. When the temperature reaches 2500° — 2700° C. the space bounded by the plate and the air convection currents set up becomes filled with a luminous vapour, which gives a spectrum of rays and bands. At 3000° C. a red fringe, also giving a spectrum of rays and bands, appears on the lower surface of and in contact with the plate, and its position can be controlled by means of a powerful magnetic field set up by an electro-magnet. (See further J. Chem. Soc., Jan., 1920.)—W. G.

Thermal conductivity of solid insulators. W. M. Thornton. Phil. Mag., 1919, 38, 705—707.

IN the case of solid insulators such as quartz, glass, graphite, paraffin wax, marble, and the like, the author finds that the thermal conductivity κ is related to the density ρ of the solid insulator, and the velocity, v , of sound therein, by the relation $\kappa = v^2 \rho^2$.—J. S. G. T.

PATENTS.

Electric furnaces. H. A. Kent, London. Eng. Pat. 133,485, 28.10.18. (Appl. 17,543/18.)

A RESISTER or crucible is mounted between conductive parts, or electrodes carried by the conductive parts, which may be partly rotated in bearings or equivalent supports, the conductive parts carrying discs or the like dipping into mercury in receptacles in connection with the electric supply mains. Means are provided for cooling the conductive parts or electrodes, and good contact is maintained between the resistor or crucible and the conductive parts or electrodes by means of a spring device.

—B. N.

Electric furnace. C. Masera, Turin, Italy. U.S. Pat. 1,320,881, 1.11.19. Appl., 9.12.18.

ELECTRODES in an electric furnace are raised or lowered by means of a terminal clamp secured to the electrode and to a ring which carries nuts through which screws pass. A cooling jacket

telescoping with the clamping cylinder is fitted on the furnace roof.—C. A. K.

Electrolytic cell. R. Q. Brown, Kansas City, Mo. U.S. Pat. 1,318,724, 14.10.19. Appl., 21.2.17.

THE cell comprises a receptacle forming the cathode, and provided at its upper end with flanges projecting outwards, a cover being bolted on, but insulated from the flanged end. A pair of bolts with angular heads is secured to and against the outer side of the cathode, and against the under side of one of the flanges, but spaced from and projecting upwards beyond the cover. The latter is provided with a bell depending into the cathode, with a sack attached to the lower end of the bell and out of contact with the cathode. The water level within the cathode is indicated by a float, and a pair of independent gas tubes are provided, within and without the bell, extending downwards but insulated from the covering, and terminating short of the lower end of the bell. A plate anode is disposed within the bell and sack, but out of contact with both, and is provided with a pair of headed bolt extensions extending up through but insulated from and clamped to the cover.—B. N.

Electrolytic cell. H. A. Hallum, Seattle, Wash. U.S. Pat. 1,318,993, 14.10.19. Appl., 30.7.18.

THE cell, acting as a negative electrode and a container for the electrolyte, is provided with an inner peripheral flange about its upper end to which is fastened a plate with apertures. A positive electrode with a threaded stem passes through and is insulated from the plate, and an oxygen bell is mounted upon, but insulated from the stem. The bell is provided with an oxygen outlet passing through an aperture in the plate, but insulated therefrom. A diaphragm secured to the marginal edge of the bell surrounds the positive electrode, and means are provided for holding the lower portion of the diaphragm spaced apart from the positive electrode.—B. N.

Electrolytic apparatus. E. A. le Sueur, Ottawa, Canada, Assignor to The Diamond Match Co., Chicago, Ill. U.S. Pat. 1,319,715, 28.10.19. Appl., 30.3.17.

A RELATIVELY heavy "feeder," provided with a support, is in electrical contact with and throughout the length of a narrow marginal portion of a metallic anode sheet, the marginal portion and the adjacent surface of the feeder being coated with insulating material. Lateral members embrace the feeder and the anode sheet, clamping together the portions in contact.—B. N.

Electrolytic method, apparatus, and product. M. M. Merritt, South Middleton, Mass. U.S. Pat. 1,322,494, 18.11.19. Appl., 15.4.19.

IN a method of depositing metal electrolytically on wire or other flexible cathode, the latter is passed in helicoidal form about two tiers of sheaves, the sheaves of each tier being free to rotate relatively to the co-operating sheaves, in order to equalise the strain on the wire, whilst the electrolyte is circulated past the runs of wire between them.

—W. E. F. P.

Electric battery. E. A. Sperry, Brooklyn, N.Y. U.S. Pat. 1,321,947, 18.11.19. Appl., 24.9.15.

A BATTERY plate is prepared by depositing lead electrolytically on a copper base provided with openings, coating the plate so prepared with lead oxide and a carbonaceous substance, and highly heating the surface of the coating.—W. E. F. P.

Electric cell. H. E. Evans, Buffalo, N.Y. U.S. Pat. 1,322,486, 18.11.19. Appl., 1.6.18.

AN electric cell consists of a receptacle containing a depolarising fluid (bichromate) in which the posi-

tive electrode (a porous carbon cup) is immersed. The latter contains a solution of sodium zincate in which the negative electrode (zinc) is suspended.

—W. E. F. P.

Gases; Apparatus for the electrical treatment of —. C. W. J. Hedberg, New Britain, Conn., Assignor to Research Corporation, New York. U.S. Pat. 1,319,706, 28.10.19. Appl., 26.2.18.

A COLLECTING electrode comprises a treater chamber and a number of vertically spaced pivoted plates having aligned orifices to form a conduit for the gases. A discharge electrode extends into the conduit, and means are provided for turning the plates about their pivots and for rapping them during the turning movement.—B. N.

Electrode. H. B. Conover, Steubenville, Ohio. U.S. Pat. 1,322,163, 18.11.19. Appl., 24.11.16.

A DISCHARGE electrode disposed centrally within a tubular collecting electrode consists of a metal rod upon which metal discs are fastened in spaced relation, the edges of each disc being rounded to increase its discharge surface.—W. E. F. P.

Electric-resistance element and alloy therefor. F. L. Driver, jun., Newark, N.J., Assignor to Driver-Harris Co., Harrison, N.J. U.S. Pat. 1,321,294, 11.11.19. Appl., 7.2.19.

AN iron alloy contains a low percentage of chromium, together with manganese and a metal such as nickel or cobalt. The nickel and manganese contents lie within the approximately constant resistance zone and may be 50% Ni and 10% Mn.

—C. A. K.

Electrode. J. C. King, Montreal, Canada. U.S. Pat. 1,322,491, 18.11.19. Appl., 21.3.17. Renewed 7.4.19.

AN electrode having a surface coating consisting of silica, 25—90, and graphite, 75—10%.—W. E. F. P.

Insulation for electrical machines and transformers; Drying —. A.-G. Brown, Boveri et Cie., Baden, Switzerland. Ger. Pat. 313,993, 14.7.17.

THE insulation of electrical machines, e.g., oil-transformers, is placed, before assembling the parts, in a heated chamber containing a hygroscopic substance for absorbing any moisture. A current of an inert gas, such as air from which the oxygen has been removed, is passed through the chamber, and thus oxidation of the oil and other insulating material is prevented.—L. A. C.

XII.—FATS; OILS; WAXES.

Cottonseed oil; Colour standards for —. H. V. Army, C. Kish, and F. Newmark. J. Ind. Eng. Chem., 1919, 11, 950—953.

It was found by Priest (Proc. Soc. Cotton Products Analysts, 1913, 6) that there were considerable variations in the colours of different standard sets of Lovibond glasses. On the other hand, it is not possible to use authentic samples of cottonseed oil as standards, since even when sealed up in vacuum cells the oils change in colour in a few months. These difficulties are obviated by the use of standard cobalt-ferric-copper solutions and ammoniacal cobalt-chromate-copper solutions, which are easily prepared, uniform, and permanent (compare this J., 1915, 925). The "Co-Fe-Cu" fluids are prepared by blending a red N/2 cobalt chloride solution in 15% hydrochloric acid (1474 grms. Co per litre) with a yellow N/2 ferric chloride solution in 15% hydrochloric acid (9308 grms. iron per litre), and a blue N/2 copper sulphate solution in 15% hydrochloric acid (158925 grms. of copper per litre). The "Co-Cr-Cu" fluids are prepared by mixing N/10 cobaltamine solution in 2.8% ammonia water (29485 grms. Co per litre) with N/10 ammonium chromate solution in 2.8% ammonia water (0.8666 gm. Cr per litre), and N/10 cuprammonium solution in 2.8% ammonia water (31785 grms. Cu per litre). Samples of these liquids mixed in various proportions had not faded to any appreciable extent after six years, showing the same values when compared with the same Lovibond glasses. In matching cottonseed oil with these standard fluids the two liquids are placed side by side in 0.5 in. cells in the Lovibond instrument. In the results of typical tests, given in tabular form, "Prime White" samples of oil were matched by blends ranging from a mixture of 6 c.c. of N/2 ferric chloride solution and 0.4 c.c. of N/2 cobalt chloride solution, with sufficient water to give 50 c.c., to a mixture of 16 c.c. of ferric chloride solution, 1.4 c.c. of cobalt chloride solution, and water to 60 c.c. Analogous limits are given for other grades of cottonseed oil. The results were in accordance with the Lovibond readings.

—C. A. M.

Oil from sumac (Rhus glabra). H. W. Brubaker. J. Ind. Eng. Chem., 1919, 11, 950.

The air-dried seeds of the common sumac (*Rhus glabra*) yielded on extraction with ether an average of 11.71% of a deep yellow oil, with pleasant odour and taste. When cooled it solidified to a semi-solid mass at -16°C ., and exposed in a thin film to the air increased 1.66% in weight in seven days, as compared with linseed oil 9.30%, and cottonseed oil 0.65% under the same conditions. It had the following average characters: Sp. gr. at 15°C ., 0.92577; refractometer reading (Abbé) at 20°C ., 1.4710; acid value, 0.9; saponif. value, 192.6; acetyl value, 9.23; iodine value, 126.78; soluble fatty acids, 0.766%; insoluble fatty acids, 93.54%. Fatty acids: M. pt., 17°C .; solidif. pt., 6°C .; refractive index, 1.470; and iodine value, 121.8. The oil is readily saponifiable, forming a semi-solid sodium soap. It might be used as an edible oil or as a semi-drying oil in the paint industry.—C. A. M.

Acetyl value [of fats]; Errors in the determination of the — and their remedy. A. Grün. Oel u. Fettind., 1919, 1, 339—341, 364—367. Chem. Zentr., 1919, 90, IV., 645—646.

The tendency of hydroxy-acids to form inner anhydrides is a source of error which is not entirely eliminated in Lewkowitsch's method of determining the acetyl value, since mixed anhydrides may be formed as in the reaction:—

When such anhydrides are formed too much acetic acid will be found by the distillation method. A more serious source of error is that caused by the formation of inner esters of hydroxy-fatty acids. For example, ricinoleic acid, after eight hours' boiling with acetic anhydride, was converted not into acetylricinoleic acid but into acetyldiricinoleic acid:—

In the case of this by-reaction the acetyl values determined by Lewkowitsch's method will be too low, whilst by Benedikt and Ulzer's method they will be too high. An objection to the ordinary methods of determining the acetyl values of neutral fats is that reciprocal esterification between the triglyceride and acetic anhydride may take place, whilst it is difficult to distinguish between the different forms of hydroxylated constituents indicated by the value. To obviate these difficulties a method has been devised in which the fatty acid esters are acetylated. These esters are prepared by heating the fat with methyl or ethyl alcohol and 1 to 2% of hydrochloric or sulphuric acid, evaporating the alcohol and neutralising, washing, and drying the residue. Neither acid anhydrides nor inner esters can be formed on acetylating these esters, which is preferably done by the original method of Benedikt and Ulzer, after removal of volatile esters. The acetyl value of free acids is obtained by multiplying the acetyl value of the esters by the theoretical acetyl value of the free acids and dividing by the theoretical acetyl value of the esters. In the case of the methyl esters, calculation into the triglyceride is unnecessary, since the difference between the groups C_3H_5 and the group C_3H_7 is negligible. For the determination of the amount of mono- and diglycerides the neutralised fat is acetylated and the acetic acid content of the product estimated. The difference between the acetyl value of the neutral fat and that of the mixture of methyl esters prepared from it corresponds to the amount of mono- and diglycerides. Acetylation of the fatty acid esters instead of the free acids or neutral fat is also advisable for the determination of the hydroxyl value.—C. A. M.

Soap; Lathering of —. J. Leimdörfer. Seifensieder-Zeit., 1919, 46, 273—274, 295—296, 317—318, 339—340. Chem. Zentr., 1919, 90, IV., 751—755.

The difference between the behaviour of castor oil soaps and that of palm-kernel and coconut oil soaps is explained by the relations of these oils towards electrolytes. The author has studied the concentrations of electrolytes required to precipitate the various soaps. Castor oil soap is the most resistant to flocculation, and is salted out only by sodium hydroxide. The reduced lathering power of the salted-out castor oil soap is connected with its high content of electrolyte. The capacity for swelling of the soap in water is lowered by the solution of the electrolyte. Stearin soap is another striking case; it is typical of those soaps in which the lathering power tends to be suppressed through the predominance of hydrolysis. Sulphonated oils, even those prepared from rape oil, are far less sensitive to electrolytes than coconut oil soaps. One hundred parts of sulphonated rape oil can substitute 110 parts of coconut oil, and 70 of sulphonated rape oil is equivalent to 100 of palm-kernel oil. Soaps made from rape oil in combination with sulphonated rape oil by the cold process have excellent lathering power and are quite hard.—J. F. B.

PATENTS.

Copra; Process of and apparatus for washing and drying —. C. P. Park, Caulfield, Victoria. Eng. Pat. 134,982, 27.11.18. (Appl. 19,609/18.)

Is apparatus for washing and drying copra the

cracked nuts are fed through a hopper on to an endless conveyor, by means of which they are carried through an alkaline solution and are then dropped through an opening in the side of a vertical dryer on to the top of a series of drying tables. The material is carried over the tables, in opposite directions on alternate tables, by means of endless conveyors. The drying vessel is heated, *e.g.*, by means of a number of coils containing superheated steam. Washing with an alkaline solution previous to drying removes "milk" from the surface and prevents the formation of fungus and mildew on copra.—L. A. C.

Oils; Refining vegetable — C. L. Riley, North Plainfield township, N.J., Assignor to Clark, MacMullen, and Riley, New York. U.S. Pat. 1,320,093, 28.10.19. Appl. 16.11.17.

A MIXTURE containing a partially-refined vegetable oil and soap is introduced into a solvent for soap, and portions of the soapy solvent are withdrawn. A fresh supply of solvent is introduced and the diluted solvent re-circulated.—B. N.

Hydrogenation catalysts; Process of re-activating spent — H. Schlinek und Co. A.-G., Hamburg. Ger. Pat. 313,192, 22.1.96.

SPENT catalyst from hydrogenation processes is freed from adherent organic matter and treated with acid in insufficient quantity for complete solution of the whole of the catalytic metal, and the dissolved portion is then reprecipitated upon the undissolved portion. The activity of the catalyst is in this way as completely restored as if the whole of the metal had been dissolved. Sodium bisulphate may be used in place of acid for dissolving the metal.—C. A. M.

Cleaning compound. L. C. Gorius and F. B. Hays, Indianapolis, Ind. U.S. Pat. 1,322,009, 18.11.19. Appl., 7.6.15. Renewed 25.4.19.

THE solid matter precipitated from a mixture of 27% to 42% of corn (maize) syrup, 25% to 28% of water, and 48% to 30% of a mixture of sodium hydroxide and soda ash in equal volumes, is separated from the liquor and mixed with two parts by weight of water to form a cleaning compound.—L. A. C.

Soap substitute. J. Perl und Co., Berlin. Ger. Pat. 313,319, 1.10.16. Addition to Ger. Pats. 308,609 and 311,160 (this J., 1919, 21 A, 545 A).

THE prepared cakes are treated with water after they have been separated for a short time in order to prevent them subsequently becoming hard. Most of the uncombined magnesium chloride is thereby dissolved away.—J. F. B.

Soap or saponaceous composition and process of manufacturing the same. W. Feldenheimer, London, and W. W. Plowman, East Sheen. U.S. Pat. 1,321,516, 11.11.19. Appl., 22.3.19.

SEE Eng. Pat. 125,491 of 1918; this J., 1919, 427 A.

Waxes, oils, etc. Eng. Pat. 133,989. See IIa.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

Hiding power of white pigments and paints. A. H. Pfund. J. Franklin Inst., 1919, 188, 675—681.

THE hiding power of a paint is defined as the thinnest layer which will hide the background as effectively as does an infinitely thick layer. A "cryptometer" for determinations of hiding power on this principle is described. A plate of glass

(14×5×0.6 cm.) has its lower surface coated with black baking enamel to serve as a black background. The upper surface is optically flat and has a transverse groove 2 mm. deep and 1 cm. wide cut in it. Another glass plate (7×3.5×0.6 cm.) with its under surface optically flat has a narrow strip of steel 0.45 mm. thick attached to one edge of its under side, and rests on the larger plate so that a wedge-shaped layer of white paint under examination may be formed between the plates. This wedge of paint terminates abruptly at the "infinitely thick" layer formed by the paint in the transverse cut, the line of demarcation being visible so long as the hiding is not complete. The wedge is moved backwards and forwards along a direction parallel to the length of the plates, and the mean of the points between which the line of demarcation with the "infinitely thick" layer is visible and that at which it disappears is taken. By taking ten pairs of readings the average deviation from the mean is found to be 3—4%. From a knowledge of the angle of the wedge and the reading of a scale on the lower plate the thickness of the critical layer lying immediately above the point found may be calculated. A viewing device consisting of an arrangement of blackened shields to cut out extraneous light and to allow the plates to be illuminated from one side of the observer only may be used. From a knowledge of the relative proportions of pigment and oil and the thickness of the critical layer, hiding powers of pigments are returned as area in sq. cm. covered by 1 gm. The hiding powers of paints are similarly returned as area in sq. ft. covered by 1 gal. In determinations of hiding powers of a number of pigments it is not expedient to prepare pigment-oil mixtures of constant numerical composition as the different "oil absorptions" of the pigments would thereby result in the production of paints of varying and in some cases impracticable consistency. A standard "painting consistency" over a range of samples is therefore aimed at, and allowances made in the calculation for the different proportions of pigments in the paints. The results for characteristic pigments and paints are given in a table in which the non-relation of the order of the hiding powers of pigments to that of their corresponding paints is noteworthy, the divergence being merely due to differences in oil absorption. Comparative determinations of hiding powers of three paints by the craftsman's method of application of a sufficient number of coats of paint to produce obliteration of a black cross on a white undercoat agreed within reasonable limits with those using the cryptometer.—A. de W.

Lead chromate; Iodometric determination of chromic acid in — M. Gröger. Z. anorg. Chem., 1919, 108, 267—272.

THE chromic acid in lead chromate can be estimated iodometrically by dissolving the chromate in hydrochloric acid if the strength of the latter is so chosen that no reduction of the chromic acid takes place. Experiments showed that when hydrochloric acid of 1.25*N* strength or less was used, in the proportion of 25 mols. HCl to 1 mol. of chromate, no reduction took place even after boiling the solution for three hours. With stronger acid, however, the rate of reduction increased rapidly with the concentration of the acid. The analysis is carried out as follows. About 0.3 gm. of the lead chromate is heated gently with 50 c.c. of 1.25*N* hydrochloric acid until all has dissolved. The solution is cooled. 1 gm. of potassium iodide added, allowed to stand for ten minutes, diluted with 100 c.c. of water and the free iodine titrated with sodium thiosulphate. The precipitated lead iodide does not interfere with the end point. A short time after the titration is finished, free iodine again appears, due to atmospheric oxidation of the hydriodic acid, a reaction which appears to be catalysed by lead iodide. This

method can be used for determining the chromic acid in basic lead chromates and in pigments containing lead chromate. The results always tend to be about 0.5% too high.—E. H. R.

Tetralin, a new turpentine substitute. Vollmann. *Farben-Zeit.*, 1919, 24, 1689—1690. *Chem. Zentr.*, 1919, 90, IV., 668.

"TETRALIN" or tetrahydronaphthalene and "tetralin extra," a mixture of tetralin with "dekalin" or decahydronaphthalene, are serviceable turpentine substitutes. Their high boiling points, by diminishing the risk of fire when working in open pans, simplify the manufacture of lacquers and varnishes, and owing to their low volatility the loss by evaporation is small. The solvent power for natural gums, coumarone, indene, and tar resins for linoxyn, oils, and fats is far superior to that of almost all known liquids. "Tetralin extra" has a somewhat smaller solvent action and higher vapour tension than pure tetralin. It is therefore to be preferred as an addition to lacquers. Lacquers prepared by the addition of "tetralin" or "tetralin extra" have excellent covering power. "Tetralin extra" behaves as an oxygen carrier.

Oil from sumac. Brubaker. See XII.

Ultramarine blue. Kalshoven. See XVII.

PATENTS.

Water-proof paint. S. Kuroki and M. Makayama. Tokyo, Japan. Eng. Pat. 135,132, 16.5.19. (Appl. 12,343/19.)

WHEAT flour (8½ lb., i.e., about 3850 grms.) is kneaded with 2000 grms. of water for two hours, and is then washed with water to remove the starch. The gluten is maintained at 75°—80° F. (about 24°—27° C.) for 5 to 7 days until a viscous liquid readily miscible with either water or oil is obtained. One part of camphor oil is added to 5 parts of the liquid, and then 3 parts of formalin is added to 10 parts of the mixture. The product may be used as a waterproof paint, or may be mixed with china clay and a pigment, dried and ground, to form a material for use in the manufacture of paint.

—L. A. C.

Shellac, resin, or the like; Production of synthetic —. (b) (c) *Substitutes for celluloid, vulcanite or the like.* W. T. Robinson-Bindley, A. W. Weller, and E. Duleken, London. Eng. Pat. 134,563, 27.2.18. (Appl. 3501/18.)

SYNTHETIC shellac, resin, or the like is obtained by adding a mineral acid catalyst, e.g., hydrochloric acid, to formaldehyde or an equivalent quantity of a substance adapted to yield formaldehyde, which is then condensed with *m*- or *p*-cresol by heating to about 80° C. The temperature is reduced when the mixture bubbles, heating being discontinued when the viscous mass separates from the cloudy liquid. The viscous mass is poured off, washed free from cresol and free hydrochloric acid by means of steam at about 120° C., and finally heated in a vacuum to extract all liquid, after which it is cast into moulds. The product may be toughened by further heating in an autoclave to about 140° C. at 100 lb. pressure whilst in the moulds. A spirit-soluble product is obtained when 70 parts of *m*-cresol is condensed with 50 parts of 40% formaldehyde and 5 parts of 30% hydrochloric acid, an oil-soluble product being produced by condensing 50 parts of *p*-cresol with 70 parts of 40% formaldehyde and 5 parts of 30% hydrochloric acid.—A. de W.

Rubber; Art of reclaiming —. C. W. Bedford. Assignor to Goodyear Tire and Rubber Co., Akron, Ohio. U.S. Pat. 1,321,501, 11.11.19. Appl., 13.4.18.

FRESH rubber stock containing added protein is vulcanised, and the product is reclaimed and re-vulcanised.—E. W. L.

Rubber; Process for regeneration of — from old rubber and scrap. W. North and H. Loosli, Hannover. Ger. Pat. 313,551, 8.8.17.

THE material is heated with water under a pressure of 200—600 atm. at a high temperature, e.g. 210° C., and in presence of alkaline substances such as caustic soda. Free and also combined sulphur as well as organic and inorganic filling materials are more completely removed than by existing processes, and the rubber is not affected.—H. J. H.

Rubber substitute and process of producing the same. M. Gregory, Tacoma, Wash., Assignor to Western Rubber Co. U.S. Pat. 1,321,788, 11.11.19. Appl., 13.3.16.

SEE Eng. Pat. 123,114 of 1917; this J., 1919, 227 A.

Vulcanite substitute. Eng. Pat. 131,561—5. See V.

XV.—LEATHER; BONE; HORN; GLUE.

Hide and pelt; Biological and chemical history of —. Relation of elastin to the tanning process. W. Möller. Collegium, 1918, 105. Chem.-Zeit., 1919, 43, Rep. 263.

THE elastin of the corium is a complex of a number of colloidal constituents. Its physical properties suggest that it has already undergone a tanning process in the living tissues, and its greater resistance, as compared with collagen, to the action of acids and alkalis is thereby accounted for. Tryptic enzymes are more active towards elastin than towards collagen. The action of the "limes" is to saponify and remove sulphur from elastin, the properties of which then approximate to those of collagen. It is necessary to de-tan these elastic fibres as completely as possible without damaging the collagen, and this is effected by the preliminary processes in the case of sole leather. In the case of upper leather the bating process almost completely removes the elastin, and it is mainly the absence of these fibres which accounts for the difference between a bated pelt and one which has only been delimed with acid, and which gives to the finished leather its characteristic "plastic" feel. It follows that hides rich in elastin tend to give a loose upper leather.—E. W. L.

Aldehyde tannage. W. Möller. Collegium, 1918, 25. Chem.-Zeit., 1919, 43, Rep., 263.

THE course of the aldehyde tannage affords evidence that chemical theories of tanning are incorrect. It is not the presence of a certain radical which determines the tanning action, but the possibility of the formation of a colloidal substance in presence of a "peptising" agent. This is shown by the fact that aromatic aldehydes do not tan when the aldehyde group is attached to the nucleus, but only when it is in an aliphatic side-chain. Tannage with aldehydes therefore depends upon the fact that by the addition of acid or alkali polymerisation and condensation are intensified and the quantity of "peptised" substance thereby increased.—E. W. L.

Gelatin jellies; Relationship between shrinking and diffusion structure in tanned —. W. Moeller. Kolloid-Zeits., 1919, 25, 101—109.

THE structures produced by the diffusion of solutions of sodium hydroxide into sodium chloride-gelatin jellies, which have been hardened by formaldehyde, are due to changes in the internal structure of the micellar envelope. The thin tanned layer attaches itself closely to the underlying coarse structure and follows completely the direction of the coarser structure. Under tension shrinkage lines are formed radially from the diffusion centre, and concentric ring systems are produced by contractions of the micellar envelope.—J. F. S.

Oil from sumac. Brubaker. See XII.

PATENTS.

Scrap and waste leather; Method of and means for the treatment and utilisation of —. S. C. Lansdown, Melbourne, and P. Magnus, North Fitzroy, Victoria. Eng. Pat. 134,592, 29.10.18. (Appl. 17,623/18.)

SCRAP leather is ground to a coarse powder, cleansed, and rendered gelatinous by treatment with a tepid 2% solution of oxalic acid, and allowed to dry in a shady place. The dried, cleansed powder (2 lb.) is mixed with 1 lb. of a mixture consisting of hot liquid glue, 85; boiled linseed oil, 10; "carbolic oil," 21; and oil of cloves, 2½. The resulting mass is formed into sheets or pieces of suitable size and thickness in moulds under a pressure of 4 tons per sq. in., the sheets being after-

wards allowed to dry in the atmosphere. The product is suitable for use for soles and heels of boots and shoes.—E. W. L.

Casein; Process for preparation of horn-like material from —. R. Weiss, Hamburg. Ger. Pat. 313,881, 29.4.17.

CASEIN is kneaded with sulphonated fatty acids, pressure and heat being applied at the same time. The use of a mixture of 3 parts of Turkey-red oil and 17 parts of water leads to products of great plasticity and strength, not brittle nor easily cracked.—B. V. S.

Plastic compositions from vegetable ivory; Manufacture of —. G. C. Devonshire, London, and E. T. Foord, Birmingham. Eng. Pat. 134,619, 5.11.18. (Appl. 18,140/18.)

Plastic material [from gelatin]. A. P. Galley, Assignor to Soc. Française du Ceramoid, Paris. U.S. Pat. 1,321,429, 11.11.19. Appl., 29.1.18.

Enzyme of soya beans. Wester. See XVIII.

XVII.—SUGARS; STARCHES; GUMS.

White sugar; Iron content of plantation —. W. H. T. Harloff. La. Planter, 1919, 63, 61—62. Int. Sugar J., 1919, 21, 574.

REFERRING to the work of Schneller and Zerban (this J., 1918, 778 A; 1919, 192 A) on the formation of colour by the reaction between ferric salts and the polyphenols present in the juice, the author considers that in the manufacture of white sugar under present conditions in Java such compounds are not of great influence. If syrups and molasses high in iron are strongly sulphited (as is common practice in some countries), the sugar crystallising from the acid liquor will contain only slight traces of iron. The yellowish tinge of plantation white sugar is probably due rather to the presence of the calcium salts of acids resulting from the decomposition of reducing sugars during heating in an alkaline medium.—J. P. O.

Ultramarine blue; its composition and examination [for use in sugar refining]. H. Kalshoven. Archief Suikerind. Nederl.-Indië, 1919, 27, 1041—1051. Int. Sugar J., 1919, 21, 575.

ACCEPTING the view that ultramarine may be regarded as a solid solution of colloidal sulphur in different substances, as silica, alumina, phosphorus pentoxide, boron trioxide, it follows that its quality is dependent more upon the manner in which the

mixing of the several ingredients is accomplished than upon their relative proportions. In the examination of ultramarine for use in sugar refining, in addition to the usual determinations of its comparative fineness and colouring power, the following tests may be applied: On boiling with water, no hydrogen sulphide should be evolved; on boiling with alcohol, and with sodium hydroxide, no colour should pass into solution; and on heating with hydrochloric acid, complete decolorisation with evolution of hydrogen sulphide should occur.

—J. P. O.

Dextrose; Action of alkaline-earth carbonates on — H. Murschhauser. *Biochem. Zeits.*, 1919, 97, 97—113.

A SOLUTION of dextrose boiled with calcium carbonate becomes brown and gradually loses its dextro-rotation, which after prolonged boiling is entirely eliminated; the sugar may even become laevo-rotatory. The reducing power of the dextrose is also diminished, but to a much smaller extent. Distilled water previously shaken with calcium carbonate produces the same change, but the reduction in the rotation becomes constant after some time because the dissolved carbonate is neutralised by the acid formed in the reaction. It is concluded that the dextrose is changed into levulose and eventually into other laevo-rotatory or weakly dextro-rotatory sugars.—S. S. Z.

Sucrose; Catalytic action of ferric oxide on — C. Thomae. *Chem.-Zeit.*, 1919, 43, 747.

SUCROSE after contact with tobacco ash is readily brought into violent decomposition by the application of a lighted match at the point of contact. This phenomenon is apparently due to the presence of ferric oxide in the tobacco ash, and sugar which has been rubbed with a piece of dry rusty iron, preferably slightly warm, can be set on fire by means of a match in a similar way.—G. F. M.

Mannitol; Physical properties of — and its aqueous solutions. J. M. Braham. *J. Amer. Chem. Soc.*, 1919, 41, 1707—1718.

PURE mannitol may be obtained from the commercial product by two crystallisations from aqueous alcohol. The pure substance melts at 166.5° C., has $[\alpha]_D^{25} = -0.244 \pm 0.002$; sp. gr. (room temperature) 1.487, specific heat $C(28^\circ \text{C.} - 100^\circ \text{C.}) = 0.3271$ cal./deg. $C(14^\circ - 26^\circ) = 0.315$ cal./deg. and heat of combustion 4.00° cal./gram.—J. F. S.

Hydrolysis of starch. Sherman and Walker. See XVIII.

PATENTS.

Sugar moulds; Method and apparatus for cooling masscuite in — G. A. Widström, Landskrona, Sweden. Eng. Pat. 109,621, 12.9.17, (Appl. 13,092/17.)

MASSECUTE contained in moulds such as are used in the Adant process of manufacturing sugar cubes, is cooled by irrigating both the cylindrical surfaces of the moulds with cold water. A rotary device, supplied from above with cooling water, is fitted centrally to a frame bolted to the top of the mould, and is easily removable. It carries two tubular arms which revolve with it and discharge the water against the inner and outer cylindrical surfaces respectively of the mould.—J. H. L.

Saccharine materials; Decolorising and purification of — J. J. Hood, London, J. Clark, Hutton, Essex, and P. G. Clark, London. Eng. Pat. 134,607, 4.11.18. (Appl. 18,042/18.)

CRUDE saccharine solutions, e.g., the juice expressed from sugar cane or beet, solutions of crystallised saccharine bodies or of artificially prepared glucose,

or the like, are filtered through or agitated with ignited precipitated magnesia, precipitated alumina, magnesite, bauxite, or mixtures of the same. In certain cases, the addition of small quantities of salts such as aluminium nitrate, aluminium chloride, calcium phosphate, sodium carbonate, or the like, to the solution before filtration increases the degree of decolorisation. The filtering medium, when it ceases to be effective, is revived by washing, and igniting at dull redness with the exclusion of air.—L. A. C.

Starch products; Process for the manufacture of — R. W. G. Stutzke, Assignor to The G.A. Buhl Co., Chicago, Ill. U.S. Pat. 1,320,719, 4.11.19. Appl., 19.8.16.

A STARCH solution is desiccated and simultaneously modified by being subjected in finely divided form to a current of heated gas.—A. E. D.

Inulin and larulose; Production of — from plant juices. A. Daniel, Charlottenburg. Ger. Pat. 313,986, 19.9.16.

By heating with strong alkalis, foreign matter is precipitated or converted into an innocuous form, the concentration of alkali being limited to a degree which prevents precipitation in the further treatment of the juice. For example, inulin is obtained by treatment of dahlia tubers with alkali hydroxides, carbonates, and alkaline earths. From pure inulin it is possible to prepare its degradation products, levulose, caramel, and dextrin.

—H. J. H.

Potato starch. Ger. Pat. 301,679. See XIXA.

XVIII.—FERMENTATION INDUSTRIES.

Hydrolysis of starch; Influence of aspartic acid and asparagin on the enzymic — H. C. Sherman and F. Walker. *J. Amer. Chem. Soc.*, 1919, 41, 1866—1873. (Compare Sherman, Walker, and Caldwell, this J., 1919, 651 A.)

THE action of saliva, pancreatin, and purified pancreatic amylase on alkali-washed potato, wheat, maize, and rice starches and on Lintner soluble starch is accelerated by the addition of small amounts of boiled, neutralised water extract of potato, whilst the action of the vegetable amylases tested was not influenced by the addition of potato extract. The addition of neutralised aspartic acid or asparagin accelerated the action of saliva, pancreatin, and purified pancreatic and malt amylases. Clear evidence of activation was not obtained in the case of malt extract or of the preparations made from *Aspergillus oryzae*. The addition of both sodium aspartate and asparagin to the same digestion mixture produces practically the same activation as does one of these substances alone, the activating effects of these substances being interchangeable rather than additive. Activation is not due in these experiments to change in hydrogen ion concentration nor merely to a more favourable concentration of electrolyte. The amino-compounds to be tested were added to a substrate which already contained the optimum concentrations of sodium chloride and phosphate, the reported activation being thus additional to the activity induced by the chloride and phosphate. Moreover, sodium aspartate is not interchangeable with sodium chloride in the activation of purified pancreatic amylase.

—H. W.

Pancreatic amylase preparations; Proteolytic activity of — H. C. Sherman and D. E. Neun. *J. Amer. Chem. Soc.*, 1919, 41, 1855—1862.

HIGH-GRADE commercial pancreatin was purified as described previously (Sherman and Schlesinger,

this J., 1915, 627; Sherman and Neun, this J., 1918, 526 A), except that in the final precipitation the usual 1:1 alcohol-ether mixture was replaced by a 2:1 mixture. A precipitate (A) was thus obtained, after removal of which a second precipitate (B) was isolated by adding more ether to the filtrate. The amylolytic activity of (A) was found to be lower than that of (B), but the latter was more active than the usual amylase preparations; the proteolytic activity was higher in precipitate (A) than in precipitate (B). Interpretation of the results is rendered difficult by the exceedingly unstable nature of the substance under purification and the impossibility of pushing the fractionation further because of the great tendency to loss of amylolytic activity when pancreatic amylase in the absence of salts and carbohydrates is held in solution or subjected to precipitation. On the whole, it seems probable that a partial separation of a mixture of amylase and protease was accomplished, but that amylolytic activity was partially lost because of the extra manipulation, since it deteriorates much more rapidly than proteolytic activity, at least under conditions such as obtained in these experiments. The further possibility that there are enzyme particles which have both amylolytic and proteolytic activities is not excluded.

—H. W.

Yeasts; Analysis of —. E. Vautier. Ann. Chim. Analyt., 1919, 1, 345—347.

THE presence of brewers' yeast in pressed yeast cannot be ascertained by determining the volume of carbon dioxide evolved when the yeast is grown in 10% sucrose solution, since, in given periods of time, both species of yeast yield the same volume of gas. Herzfeld's method may be used as a qualitative test for the purpose. The yeast is added to 1% raffinose solution contained in an Einhorn fermentation apparatus and maintained at 30° C. for 24 hours. If the sample consists of pressed yeast, the sugar is not attacked, but if of brewers' yeast, or a mixture of the same with pressed yeast, the sugar is fermented and carbon dioxide evolved. A control test is run at the same time, using the same weight of yeast and water, but no raffinose. A correction may thus be made for any carbon dioxide evolved as the result of auto-digestion of the yeast. An approximately quantitative test has been proposed by Bau, as follows: 10 c.c. of 1% raffinose solution is placed in each of three test-tubes, to each is added 0.4 gm. of the yeast, and the mixtures are kept at 30° C. After 24 hrs. the contents of one tube are filtered and 3 c.c. of the filtrate is heated with 1 c.c. of Fehling's solution for 5 mins. in a boiling water-bath; if the blue colour is not discharged, the yeast contains at least 10% of brewers' yeast. Should the colour of the Fehling's solution be destroyed, showing that raffinose is still present, the contents of the second tube are tested similarly after 48 hrs.; the non-discharge of the colour of the Fehling's solution in this case indicates the presence of about 5% of brewers' yeast. A blue coloration in the third test after 72 hrs. incubation shows that the yeast contains about 1% of brewers' yeast. If the Fehling's solution remains blue in this third day test, the yeast is free from brewers' yeast.—W. P. S.

Glycerol; Mechanism of the "fixation" method of the decomposition of sugar into acetaldehyde and— C. Neuberg and J. Hirsch. Biochem. Zeits., 1919, 98, 141—159.

At every stage during the process of fermentation of sugar in the presence of sodium sulphite, acetaldehyde and glycerol are produced in equimolecular proportions. As alcohol and carbon dioxide are also produced independently at the same time in equivalent proportions, the fermentation process can be followed by estimating the alcohol and aldehyde at the various stages.—S. S. Z.

Soya-bean extract [urease]; Peculiarity of —on heating at 37° C. D. H. Wester. Chem. Weekblad, 1919, 16, 1461—1463.

If the extract is heated for 3 days at 37° C., its urease-activity is reduced. Further treatment at this temperature does not uniformly reduce its enzymic action, the graph representing the urea equivalents after various periods of heating being a zig-zag.—W. J. W.

Enzyme action; Urease and the radiation theory of — H. P. Barendrecht. Proc. K. Akad. Wetensch., 1919, 22, 29—45.

THE addition of 5% alcohol to urea solutions reduces the activity constant of the urease hydrolysis from 0.00381 to 0.00335. Above a definite concentration of urease the specific activity is constant, but below this value it decreases. (See also J. Chem. Soc., Jan., 1920.)—J. F. S.

Soya-beans; Enzyme of — [Urease.] D. H. Wester. Chem. Weekblad, 1919, 16, 1442—1443.

THE author has investigated the factors which influence the conversion of urea into ammonium carbonate by means of urease. The urea solution must always be freshly prepared; but urease solutions retain their activity on keeping. The concentration of the urea does not influence the process, nor do decomposition products formed act deleteriously. Glycerin may be added to the medium used for extracting urease from soya beans up to 50% of its volume; larger quantities reduce the urease content, and addition of glycerin to the urease-urea mixture retards enzymic action. The extract of canavalia beans is in some respects similar to that obtained from soya beans.

—W. J. W.

Methyl and ethyl alcohols; Differentiation of — Panwitz. Pharm. Zentr., 1919, 60, 441—442.

COPPER sulphate is insoluble in ethyl alcohol, but dissolves in anhydrous methyl alcohol, giving a blue solution. The presence of a small quantity of water, however, destroys the blue coloration, and the quantity of added water must be increased to 35% by volume before the blue colour reappears. At this dilution, ethyl alcohol also dissolves copper sulphate, and the test is therefore untrustworthy for distinguishing between the two alcohols. Water also interferes with the borax flame test for methyl alcohol.—W. P. S.

PATENTS.

Cellulose; Fermentation of — [for the production of acetic acid]. Power Gas Corporation, Ltd., and H. Langwell, Stockton-on-Tees. Eng. Pat. 134,265, 1.10.18. (Appl. 15,942/18.)

A MASH of cellulosic material, such as sulphite pulp or straw, is inoculated with fermenting vegetable matter, e.g., stable manure, and maintained under aerobic conditions at a temperature between 25° and 60° C. The cellulose undergoes acetic fermentation, and calcium carbonate or other suitable substance is added to neutralise the acid as it is produced. The mash must contain nutrient salts and nitrogenous matter, and some sugar or other readily fermentable substance may be added to induce a vigorous fermentation at the commencement. The temperature employed, within the limits stated above, influences the rate of fermentation, but not the yield of acid.—J. H. L.

XIXA.—FOODS.

Aluminium vessels; Use of — in dairies. Utz. *Z. angew. Chem.*, 1919, 32, 345—346.

ALUMINIUM is not attacked at ordinary temperature by 1% lactic acid solution and only very slightly dissolved when in contact with the solution at 100° C. (about 0.07 grm. in 10 hrs.); serum from spontaneously curdled milk has still less action. The quantities of dissolved aluminium are not injurious to health, and aluminium vessels may be used without hesitation for the storage, transportation, etc., of milk and milk products.—W. P. S.

Bacteria found in milk; Study of the alkali-forming —. S. H. Ayers, P. Rupp, and W. T. Johnson, jun. *U.S. Dept. Agric., Bull.* 782, 1919, 39 pages.

The group of bacteria studied is defined as consisting of those which produce an alkaline reaction in milk without peptonisation of the casein. This group produced the reaction in five days at 30° C. The reaction was not due to ammonia, as ammonia was produced by a few cultures only, and then not until after more than seven days. All the citric acid in the milk was used up and an amount of carbonate corresponding to about half the citric acid was produced. The chief sources of these organisms were milk, soil, and water. Of the species studied 6 were cocci and 62 were bacilli; all were non-sporing. The action of each organism on certain organic compounds was examined, using cultures in a sodium ammonium phosphate medium containing the substance to be tested as the only source of carbon. The change in the hydrogen-ion concentration in the medium was taken as the measure of the alkalinity produced. Dextrose and galactose were fermented by 44 cultures, lactose by 11, sucrose by 2, and raffinose by none. Ethyl, propyl, and amyl alcohols were more readily fermented than mannitol and glycerol. Most of the organisms fermented the sodium salts of pyruvic, citric, malic, lactic, succinic, acetic, propionic, butyric, valeric, caproic, mucic, glyceric, tartaric, malonic, formic, benzoic, and salicylic acids, but oxalic and glycollic acids were unacted on. It was found that urea, uric acid, and hippuric acid could act as the sole sources of both carbon and nitrogen, and also that the organisms could utilise the nitrogen in nitrites and nitrates. (See also *J. Chem. Soc., Jan.*, 1920.)—J. H. J.

Milk analysis; Application of Ackerman's refraction method to —. H. Langkammerer. *Milchw. Zentr.*, 1919, 48, 249—254.

The formulæ given by Wiegner (this J., 1910, 1076) for calculating the non-fatty solids of milk from the refractive index of the milk serum have been applied to milks of various districts and the results obtained compared with those found by the use of Ackermann's formula (*loc. cit.*). Generally, the results agree, but with some milks (from the Frankfurt district) there is a distinct difference; the winter milk contains, apparently, 0.25% more albumin than does the summer milk.—W. P. S.

Milk; Determination of added water in —. J. Goldan, jun. *Ann. Chim. Analyt.*, 1919, 4, 342—345.

WHEN corrected for the volume of fat and casein, the "simplified molecular concentration constant" (see Ferris, this J., 1917, 1245) affords a trustworthy indication of the presence or absence of added water in milk. For genuine milks the value does not fall below 70, the average value being 74. It shows less variation than do the usual analytical values for genuine milks.—W. P. S.

Butyrometer; Composition of the sediment obtained in Gerber's —. F. Reiss and G. Diesselhorst. *Milchw. Zentr.*, 1919, 48, 237—238.

THE small quantity of heavy sediment which is found at the bottom of the centrifuge tube in Gerber's method for the determination of fat in milk consists of hydrated calcium sulphate, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$; it is free from calcium phosphate.—W. P. S.

Butter fat; The Crismer value of —. L. Vandam. *Ann. Falsif.*, 1919, 12, 260—269.

THE Crismer value (critical temperature of solution) of butter fat is determined with alcohol containing 0.9% by weight of water (sp. gr. 0.7976 at 15°/15° C.), but alcohol of other strength may be used provided that the amount of water it contains is known and a correction applied to the results obtained. A mixture of petroleum and vaseline may be employed for determining the quantity of water in alcohol; this mixture is standardised against alcohol-water mixtures of known composition by determining its critical temperature of solution in the same. The results are plotted in a curve and reference to this will give the strength of any alcohol when tested with the petroleum mixture. The following corrections are applied to the Crismer values of butter fats determined with alcohols of various strengths in order to obtain the true Crismer value: For each 0.1% of water between 0 and 0.4%, +1.0; between 0.5 and 0.8, +0.9; between 1 and 1.1, -0.9; between 1.2 and 2.3%, -0.8; between 2.4 and 2.9%, -0.7. The Crismer value decreases as the acidity of the fat increases; this influence is corrected by adding to the value found the number of c.c. of N/10 sodium hydroxide solution required to neutralise 4 grms. of the fat.—W. P. S.

Yeast; Process of treatment of brewers' or distillers' — whereby an article of food is obtained resembling extract of meat. J. J. C. A. and F. M. O'Sullivan, Wolsley Bridge, Staffs, and M. L. Marsan, Paris. *Eng. Pat.* 131,168, 30.4.19. (Appl. 10,715/19.)

A MODIFICATION of *Eng. Pat.* 19,161 of 1897 (this J., 1898, 784). Pressed yeast, after undergoing autolysis, is introduced into boiling water and subjected to successive boilings and skimmings, with stirring after each removal of scum, whereby the bitter constituents are completely removed. For example, after the first boiling and skimming the liquid is filtered and again boiled for several hours and skimmed, then left to ripen for some days, and finally concentrated in an open, jacketed pan, with constant stirring, the scums which form being carefully removed. Concentration is continued until the product sets to a solid mass on cooling. Throughout the process the material should be exposed to daylight as far as possible.—J. H. L.

Granulating or finely dividing pasty or semi-fluid materials [e.g. milk]; Apparatus for —. J. C. MacLachlan, St. Paul, Minn., U.S.A. *Eng. Pat.* 134,761, 29.1.19. (Appl. 10,619/19.)

THE liquid, e.g. milk, is discharged through a rotating spraying head at the top of a condensing or evaporating chamber, through which it falls as

rain, meeting warm air moving upwards. The partially evaporated liquid is withdrawn by a pump from the conical bottom of the chamber and passed again through the same chamber or through a second similar chamber, wherein it is completely dried. The rotary spraying head consists of a propeller with downturned overlapping blades, which are rotated at a very high speed, and the liquid which is fed through the hollow spindle is emitted from holes which are not exactly on the axis of the beater, and is thrown by centrifugal force violently against the revolving arms. In addition to a current of hot air induced by external means, the beaters may draw in supplementary currents of cold air through adjacent ducts.—B. M. V.

Sterilising and preserving milk and other fluids; Method and apparatus for —. J. F. Moscrop, Omaha, Nebr. U.S. Pat. 1,319,238, 21.10.19. Appl., 21.3.19.

A TANK constructed of insulating material has baffles of insulating material standing on the bottom and secured alternately to opposite sides of the tank. Vertical conducting plates are placed close together between and with their ends in contact with the baffles, alternate plates standing on the bottom of the tank and the others being spaced therefrom. Alternate plates are connected to different poles of a source of electricity.—J. H. J.

Drying alimentary and other substances; Apparatus for —. A. F. Spawm, Los Angeles, Cal. U.S. Pat. 1,318,931, 11.10.19. Appl., 27.11.18.

A CHAMBER is supplied with heated air from a furnace at one end by flues passing along the bottom. It is divided by a vertical partition into two compartments, which are connected together at the end farthest from the furnace. Drying trays are supported in tiers in each compartment.—J. H. J.

Foodstuffs; Process for preparing — in the manufacture of potato starch. Stärke-Zuckerfabrik A.-G. vorm. C. A. Koehlmann und Co., Frankfurt. Ger. Pat. 301,679, 4.4.16.

THE juice of the potatoes is separated by pressing and is then evaporated and dried. The potatoes, after removing the juice, are used for the production of starch, mixed with pressed or dry pulp, and again dried. The evaporation residue from the juice is mixed.—A. B. S.

Feeding stuff; Production of a meal for use as — from the green parts of plants, especially foliage leaves. Versuchsstation für die Konservindustrie, Berlin. Ger. Pat. 302,426, 17.4.17.

THE material is extracted with alcohol of definite strength (88—92%) at temperatures below freezing point (–1 to –3° C.), whereby only the resinous and colouring matters are removed whilst the fats remain undissolved. Maple-leaf meal prepared in this way contains 17.91% of mineral matter, 24.18% of protein, 2.65% of fat, 24.88% of crude fibre, and 32.98% of nitrogen-free extractives.

—J. H. L.

Milk; Process for removing cream from —. R. Clavel, Basle, Switzerland. Ger. Pat. 314,090, 24.1.18. Int. Conv., 28.11.17.

MILK is converted into a froth by passing gases through it and is then poured on to a sieve whereby the cream is separated from the milk on account of its lower surface tension. By treating the separated milk intensively with gases casein and albumin may be separated in a similar manner.

—A. B. S.

XIXB.—WATER PURIFICATION; SANITATION.

PATENTS.

Water purifying and filtering device. E. L. Brillhart, Chicago, Ill., Assignor to Electric Specialty Co., New London, Wis. U.S. Pat. 1,320,118, 28.10.19. Appl., 13.8.17.

A STREAM of water is directed spirally round the inside of a tank and around and between electrodes placed therein in a diametrical plane. From the tank the water passes through scum tanks and filter tanks. Means are provided for reversing the flow through the scum and filter tanks.—J. H. J.

Garbage; Process of treating — and production of carbonic acid gas therefrom. F. Danks, Troy, N.Y. U.S. Pat. 1,319,515, 21.10.19. Appl., 1.4.18.

GARBAGE is degreased, disintegrated, and comminuted, then washed and pressed. The expressed liquid is boiled with dilute acid until the carbohydrates are converted into sugar, then neutralised and fermented, the carbon dioxide evolved being collected.—J. H. J.

Hypochlorite preparations; Process for the production of stable solid — for wound treatment. Farbenfabriken vorm. F. Bayer und Co., Leverkusen. Ger. Pat. 309,106, 15.3.17.

CALCIUM hypochlorite or bleaching powder is mixed with an acid salt, such as acid sodium sulphate, acid sodium oxalate, or acid sodium phosphate. For use the mixture is treated with water or other suitable solvent, a weakly acid hypochlorite solution being obtained which has less irritant action in wounds than has the solution of the calcium salt itself.—B. V. S.

Arsenate of lead [; Preparation containing —]. H. B. Goodwin, Grand Junction, Colo., Assignor to The Latimer Chemical Co. U.S. Pat. 1,322,008, 18.11.19. Appl., 5.8.18.

SUFFICIENT tannin is mixed with lead arsenate to increase its capacity of remaining suspended in water.—L. A. C.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Glucosides; Distillation of certain — under diminished pressure. A. Pictet and H. Goudet. Helv. Chim. Acta, 1919, 2, 698—703.

THE distillate obtained from salicin consisted of an aqueous liquid containing a little furfural and a pasty mass from which levoglucosan, m. pt. 179°—180° C., $[\alpha]_D^{20} = -66.73^\circ$ in aqueous solution, was isolated. Similarly, arbutin gave an aqueous portion containing acetic acid and furfural and a pasty mass from which levoglucosan and quinol were obtained, whilst phloretic acid, phloroglucinol, and levoglucosan were isolated from the semi-solid product from phloridzin. The authors suggest that the glucosides are in general derivatives of levoglucosan (thus accounting for their laevo-rotatory power) and not of dextrose, which is only formed as a secondary product of their hydrolysis in acid solution. (See also J. Chem. Soc., Jan., 1920.)

—H. W.

Quinoline bases; Modification of Skraup's synthesis for preparing —. Their conversion into stannichlorides. J. G. F. Druce. Chem. News, 1919, 119, 271—273.

THE method adopted for the synthesis of quinoline from aniline stannichloride (Chem. News, 1918, 117,

346) has been applied successfully, though with diminished yields, to the synthesis of its homologues from aniline homologues. Thus the *o*-, *m*-, and *p*-toluidine stannichlorides, heated with glycerol and sulphuric acid for 2–3 hours and then diluted and diazotised with sodium nitrate gave respectively 8-, 7-, and 6-methylquinoline. The stannichlorides of *m*- and *p*-phenylenediamine gave, on the other hand, very poor yields of phenanthroline and 2-phenanthroline respectively. The stannichlorides of the methylquinolines were prepared by adding stannic chloride to a hydrochloric acid solution of the base. The chlorine in these salts, and also in similar tin salts of both aromatic and aliphatic bases, was estimated with a fair degree of accuracy by simple titration with *N*/10 sodium hydroxide with phenolphthalein as indicator. (See further J. Chem. Soc., 1920, i., 88.) —G. F. M.

Optical isomers; Properties of — from the biological side, A. R. Cushny. Pharm. J., 1919, 103, 483–484.

THE power possessed by moulds and bacteria of discriminating between optical enantiomorphs is also shared by certain tissues of the higher mammals. The nerve ends appear to be the most susceptible of discrimination, whilst such tissues as the brain and muscle seem to be acted upon equally by both isomerides. Organs capable of differentiation must themselves be optically active, and it is noteworthy that in the large majority of cases the optical isomeride which occurs in nature is the one which is reactive towards, or is destroyed by, the living organism, the artificial enantiomorph being immune, or nearly so, from attack. Thus, *l*-asparagine is sweet to the taste, whilst the artificial *d*-asparagine is non-reactive and tasteless. Similarly, *l*-hyoscyamine paralyses the peripheral nerve ends, whilst atropine (*dl*-hyoscyamine) is only half as powerful and *d*-hyoscyamine has only about 1-50th the power of the *l*-isomeride. On the other hand, atropine is more active on the spinal cord of the frog than *l*-hyoscyamine and the *d*-isomeride appears therefore to be stronger than the *l*-isomeride in this case. Adrenaline from the suprarenal gland is laevo-rotatory and causes twice the rise in blood pressure produced by a similar quantity of synthetic adrenaline. It is only possible to produce an optically active substance either directly or indirectly through the agency of life, and optical activity is the most persistent evidence of life which we possess. The optical activity of petroleum is evidence that it must have originated from living tissues.—G. F. M.

Arsenicals for chemotherapeutic research; Plan of procedure for the syntheses of —. Aromatic arsenic compounds. I. W. A. Jacobs and M. Heidelberger. J. Amer. Chem. Soc., 1919, 41, 1581–1587.

THE general plan of a very comprehensive study of the chemotherapeutic value of arsenic compounds is developed. The authors consider that the Salvarsan type of these substances has been fully investigated and therefore turn their attention to products containing quinquavalent arsenic, using, as starting point, *p*-amino- or *p*-hydroxy-phenyl-arsonic acid or a similar derivative, and uniting this with an accessible group of simple type which is readily capable of chemical modification. They regard simplicity in chemical manipulation as a further essential to success. From these points of view, the following classes of compounds have been studied: diazoamino-compounds $A-N:N'NR'$ (in which A is the arylarsonic radical and R and R' hydrogen, alkyl, aryl, or substituted aryl groups); azo dyes, $A-N:N-R$ (in which R is the aromatic

coupler); *N*-substituted amides of *N*-phenylglycine-*p*-arsonic acid, $A-NH-CH_2-CONRR'$ (in which R and R' are hydrogen, alkyl, aryl, or substituted aryl groups); β -substituted ureides of *N*-phenylglycine-*p*-arsonic acid, $A-NH-CH_2-CONH-CONHR$; substituted *N*-phenylglycyl-derivatives of arsanilic acid, $A-NH-CO-CH_2-NHR$; substituted α -phenylglycollyl-derivatives of arsanilic acid, $A-NH-CO-CH_2OR$; and substituted amides of α -phenylglycollic acid *p*-arsonic acid; $A-\alpha-CH_2-CONHR$. Of these the third type has up to the present yielded the most important results.—H. W.

N-Arylglycinecarsonic acids; Amides and alkyl-amides of —. Aromatic arsenic compounds. II. W. A. Jacobs and M. Heidelberger. J. Amer. Chem. Soc., 1919, 41, 1587–1600. (Compare preceding abstract.)

THE condensation of sodium arsanilate with chloroacetic acid to yield phenylglycine-*p*-arsonic acid has been described previously (Ger. Pat. 201,644); it is now found that reaction occurs readily between sodium *p*-aminophenylarsonate, *o*-arsanilate, or certain aminotolylarsonates and the amide or alkylamides of chloroacetic acid, yielding substances of the general formula,

in which R and R' may be hydrogen, alkyl, benzyl, or substituted benzyl groups. The best experimental conditions consist in boiling aqueous solutions of the salt and the simpler chloroacetyl-alkylamines for $\frac{1}{2}$ –2 hours; in the case of the chloroacetylbenzylamines, 50% alcohol is the most serviceable medium and the addition of sodium iodide is found to be necessary. All the glycine-amidearsonic acids are colourless substances which are generally sparingly soluble in the usual neutral media and possess high melting or decomposition points, the latter depending greatly on the rate of heating. They dissolve in alkalis or alkali carbonates to form neutral salts from which they are entirely displaced by acetic acid. They are more feebly basic than arsanilic acid itself, their hydrochlorides being stable only in the presence of concentrated hydrochloric acid. On boiling with excess of alkali or with mineral acids, the amide linking is hydrolysed with formation of the glycine-arsonic acid and the amine. (See also J. Chem. Soc., Jan., 1920.—H. W.)

N-Arylglycinecarsonic acids; Ureides and β -substituted ureides of —. Aromatic arsenic compounds. III. W. A. Jacobs and M. Heidelberger. J. Amer. Chem. Soc., 1919, 41, 1600–1610. (Compare preceding abstracts.)

BY replacing the amides of chloroacetic acid by the ureide and its alkyl or aryl derivatives in the reaction described in the preceding abstract, the ureides and substituted ureides of arylglycine-arsonic acids,

(where R may be hydrogen or an alkyl or aryl radical) are obtained. The new series of substances closely resembles the amide series; they form stable and soluble neutral salts with the alkali metals. The ureide linkage, like that of the amides, is easily ruptured, this often occurring even at room temperature in solutions containing an excess of fixed alkali. A lengthy series of compounds derived from *o*-, *m*-, and *p*-arsanilic acid and from methyl-substituted arsanilic acids has been prepared, the most interesting member of which from the physiological point of view is the methylureide of *N*-phenylglycine-*p*-arsonic acid, since it has been found to exert a definite therapeutic effect in experimental syphilis and trypanosomiasis in rabbits. (See also J. Chem. Soc., Jan., 1920.)—H. W.

N-Arylglycinearsonic acids; Aromatic amides of —. Aromatic arsenic compounds. IV. W. A. Jacobs and M. Heideberger. J. Amer. Chem. Soc., 1919, 41, 1610—1644. (Compare preceding abstracts.)

A VERY extensive series of compounds, derived from *o*-, *m*-, and *p*-arsanilic acids and from methyl-substituted *p*-arsanilic acids, has been prepared in accordance with the general scheme:

In the cases of the more reactive chloroacetyl derivatives, reaction may be effected in boiling aqueous solution, but, with the more stable compounds, 50% alcohol is a more suitable solvent and sodium iodide should be added. In general, it is found that *m*-arsanilic acid condenses more readily than the *o*- and *p*-isomerides. The compounds have generally weakly basic and acidic functions; the free arsonic acids do not as a rule possess sharp melting or decomposition points, the values obtained depending greatly on the rate of heating. They are, on the whole, but sparingly soluble in the usual media. The sodium salts, on the other hand, dissolve more or less readily in water, and were prepared for convenience in biological testing and also as a means of purifying the compounds. (See also J. Chem. Soc., Jan., 1920.)—H. W.

Arsenic compounds used as drugs; Behaviour of certain organic — in Marsh's apparatus. D. Ganassini. Boll. Chim. Farm., 1919, 58, 385—390.

THE introduction of platinum chloride into the hydrogen flask of Marsh's apparatus retards or prevents the appearance of the arsenic deposit in the case of cacodylic acid. In the presence of a large excess of platinum chloride cacodylic oxide forms a yellow precipitate of cacodyl platino-chloride. If, however, only a small amount of platinum chloride is introduced, cacodylic oxide is evolved sooner or later. Even for the detection of mineral arsenic it is not advisable to use platinum chloride, since arsenic may be fixed as platinum arsenide, with a loss of as much as 50% of the arsenic present. The yellow ring, probably of erythrasine, produced, together with the ordinary black deposit, by cacodylic acid in the Marsh test is a characteristic reaction. It may be obtained quantitatively by immersing the evolution flask of Marsh's apparatus in a bath of molten lead (about 335° C.). Atoxyl and salvarsan give the ordinary arsenic deposit in Marsh's test, but neosalvarsan and methylarsinic acid behave in an analogous manner to cacodylic acid, giving a yellow ring under the same conditions. In the case of cacodylic acid, however, the gas forms dense white fumes, and when conducted into Bettendorf's reagent (stannous chloride solution saturated with hydrogen chloride) it does not form a yellow precipitate. In the case of methylarsinic acid the formation of the yellow ring is not accompanied by the appearance of white fumes, and the gas gives an abundant precipitate with Bettendorf's reagent. The lemon-yellow ring given by neosalvarsan may be distinguished from the other two by the fact that it is only formed at a high temperature, does not change to black, and is rapidly dissolved by ammonia solution. (See also J. Chem. Soc., Jan., 1920.)—C. A. M.

Tyrosine; Quantitative estimation of — by means of Millon's reaction. M. Weiss. Biochem. Zeits., 1919, 97, 170—176.

A 1/50,000 SOLUTION of tyrosine to which Millon's reagent is added is used as a standard. The solution to be examined is diluted until it gives with Millon's reagent a coloration equal to that of the

standard. The method can be employed for the estimation of tyrosine in hydrolysed proteins.

—S. S. Z.

Saccharin-bicarbonate tablets (110); Chemical alteration in the composition of —. O. Beyer. Chem.-Zeit., 1919, 43, 751—752.

SACCHARIN-BICARBONATE tablets (110 strength) after keeping several months are soluble in water with difficulty and without effervescence. Analysis indicates a corresponding diminution in carbonate radicle and in free saccharin, the latter falling in 12 months from 20% to as low as 0.58% in some cases. Even in the freshly made tablets a certain amount of the saccharin is combined, the quantity varying from 3 to 5% after 14 days. By mixing and compression, therefore, the formation of the soluble sodium sulphinate and liberation of carbon dioxide is already induced, and this continues progressively on keeping the tablets, until eventually, when nearly all the saccharin is in combination, there is practically no evolution of gas on placing the tablet in water, and, its disintegrating influence being removed, the rate of solubility of the tablet is accordingly reduced.—G. F. M.

Cyclohexanones; Transformation of — into catechols. G. Cusmano. Atti R. Accad. Lincei, 1919, 28, ii., 30—33.

METHYLSOPROPYLCATECHOL, $\text{C}_{10}\text{H}_{14}\text{O}_2$, may be obtained by heating monobromo-Buchu-camphor above its melting point, while its diacetyl-derivative is formed when the same bromo-compound is heated with acetic anhydride and sodium acetate. (See also J. Chem. Soc., Jan., 1920.)—T. H. P.

Formaldehyde; Colour reactions of — with certain aromatic compounds. A. Rossi. Boll. Chim. Farm., 1919, 58, 265—270.

SOLUTIONS of a few centigrams. of the following ten aromatic compounds in sulphuric acid give colour reactions with 0.1% and 0.001% solutions of formaldehyde. Gallic acid gives a red-brown ring at the zone of contact of the liquids, and on shaking the tube a green liquid changing to grey-green is obtained. Tannic acid gives a red-brown ring, whilst on mixing the colour is greenish-blue at the bottom, and subsequently brownish-red throughout. Pyrogallol gives a wine-red ring and red-brown liquid. The test is capable of detecting 0.00001% of formaldehyde. Salicylic acid gives a light-rose coloured ring and solution. Catechol gives a violet-red ring and wine-red liquid, and resorcinol a wine-red ring and liquid. β -Naphthol gives a violet-red ring, whilst the liquid becomes brownish-black with green fluorescence, and similar colorations are obtained with benzonaphthol. Phenyl salicylate gives a carmine-red ring and a reddish-yellow liquid, becoming pink on dilution. Phenolphthalein does not form a ring, but gives an orange liquid changing to carmine-red when shaken. On dilution with water a carmine precipitate separates whilst the solution remains colourless.—C. A. M.

Acrolein; Stabilisation of —. III. Preparation of acrolein. C. Mouren and A. Lepape. Comptes rend., 1919, 169, 885—889.

A MIXTURE of potassium bisulphate and potassium sulphate in the proportion of 5:1 is recommended as a dehydrating agent in the preparation of acrolein from glycerol. To such a mixture is added one-quarter of its weight of glycerol, and the whole is gradually heated until the reaction commences, the temperature during the greater part of the operation remaining at 195° C. The vapours first pass through a condenser so regulated that the uncondensed vapours issue from it at about 70° C. These then pass to a second condenser, from which the

acrolein is collected. As the reaction proceeds and the glycerol becomes used up more is added, until the dehydrating agent has decomposed nearly ten times its weight of glycerol. By this method 2311 kilos. of glycerol was dehydrated by 240 kilos. of the dehydrating agent and gave a yield of pure acrolein equivalent to 67.5% of the theoretical yield.—W. G.

Rose oil: German extracted —. F. Elze. Chem.-Zeit., 1919, 43, 747.

OIL of rose obtained in 0.015% yield by extraction with volatile solvents had the following constants: Sp. gr. = 0.9894 at 20° C., $n_{D,20} = +0.6^\circ$, acid value 3.15, ester value 2.9, acetylation value 317.5. Phenylethyl alcohol was the chief constituent, and in addition geraniol, citronellol, nerol, and the aliphatic sesquiterpene alcohol, farnesol, were identified. The stearopten contained several olefinic hydrocarbons with melting points ranging from 20° to 46° C.—G. F. M.

Colloidal copper. Protective colloids. Second Series. Cetraria islandica as protective colloid. IV. A. Guthrie and E. Sauer. Kolloid-Zeits., 1919, 25, 145–153.

COLLOIDAL solutions of copper may be prepared by reducing an ammoniacal solution of copper sulphate with hydrazine hydrate in the presence of a 0.2% solution of the aqueous extract of Iceland moss. The sols are fairly stable, but in 14 days' deposit a reversible gel. Sols which have a clear red colour both by reflected and transmitted light deposit reversible gels, whilst those which are turbid by reflected light deposit irreversible gels. The solid colloid is obtained by adding $\frac{1}{2}$ –1 volume of alcohol, filtering under pressure and drying in a vacuum over sulphuric acid. The limit of reversibility in the solid product is reached with 13.43% of copper. (See also J. Chem. Soc., Jan., 1920.)

Nitrobenzoic acids. Bigelow. See III.

Colloidal mercury. Guthrie and Weise. See XI.

PATENTS.

Choline; Manufacture of salts or compounds of — and of its higher homologues. J. Y. Johnson, London. From Verein. Chem. Werke A.-G., Charlottenburg, Germany. Eng. Pat. 8031, 30.3.14.

CHOLINE, or a higher homologue, is combined with suitable acids, other than hydrochloric, hydrobromic, nitric, hydriodic, chloroplatinic, or sulphuric acids. The aqueous solutions of the resulting compounds, whilst having the same effect on the cells as choline solutions when injected into the blood, are more certain in action owing to their greater stability and the consequent non-formation of poisonous decomposition products. Suitable acids are, for instance, boric, salicylic, *o*-, *m*-, or *p*-iodobenzoic, *p*-aminophenylarsonic, 4-amino-3-iodophenylarsonic, and formic acids, and the compounds or salts are produced by dissolving either an equivalent proportion or an excess of the acid in an aqueous or alcoholic solution of choline, or a higher homologue.—G. F. M.

Synthetic drugs [adrenaline]; Manufacture of —. E. C. R. Marks, London. From N. Nagai, Tokyo, Japan. Eng. Pat. 118,298, 13.7.17. (Appl. 10,183/17.)

DIACETYLPROTocatechic aldehyde, produced by the interaction of protocatechic aldehyde and acetyl chloride or acetic anhydride, is condensed with nitromethane by the action of a solution of a weak alkali, such as an alkali carbonate or bicarbonate, pyridine, etc., at normal temperature, on equimolecular proportions of the two substances. The

condensation product, diacetoxyphenylmethanol, $(CH_3COO)_2C_6H_3CH(OH)CH_2NO_2$, which separates in crystalline form, is filtered off, washed free from unchanged protocatechic aldehyde with ether and treated with acetic acid and zinc dust in presence of a 35% formaldehyde solution containing one molecular equivalent of formaldehyde, whereby simultaneous reduction and methylation take place with the production of diacetoxy-phenyl-methylaminoethanol,

The zinc is precipitated from the reaction mixture as sulphide and to the filtered solution the requisite amount of hydrochloric acid is added to effect hydrolysis and combine with the liberated base. On evaporation at a low temperature in a vacuum crystals of dihydroxyphenylmethylaminoethanol hydrochloride (adrenalin hydrochloride) are obtained.—G. F. M.

β -Halogen-ethylaminobenzoic esters; Manufacture of —. Soc. Chim. des Usines du Rhône, Paris. Eng. Pat. 128,553, 30.5.19. (Appl. 13,761/19.) Int. Conv., 20.6.18.

β -HALOGEN-ETHYL-*p*-AMINOBENZOIC esters of the general formula, $NHCH_2CH_2X.C_6H_4.CO_2R$, where X is a halogen, are obtained by treating the corresponding hydroxyethyl compounds with halogenating reagents, such as phosphorus or sulphur halides, thionyl chloride or bromide, etc. For example, ethyl β -hydroxyethyl-*p*-aminobenzoate is treated with an equal weight of phosphorus pentachloride in presence of dry benzene, the reaction is completed by heating on a water-bath, and, after evaporating off the benzene and phosphorus oxychloride, the residual chloro-ester is purified by distillation under reduced pressure. It is a crystalline substance, m.p. 69° C., and boiling at 183° C. at 3 mm. pressure. Alternatively thionyl chloride might be used to produce the same compound with dimethylaniline as a diluent.—G. F. M.

β -Alkylaminoethylaminobenzoic alkyl esters; Manufacture of —. Soc. Chim. des Usines du Rhône, Paris. Eng. Pat. 128,554, 30.5.19. (Appl. 13,762/19.) Int. Conv., 20.6.18.

β -ALKYLAMINOETHYL-*p*-AMINOBENZOIC acid esters are obtained by heating for several hours in a closed vessel at a temperature of about 100° C. a mixture of an alkylamine and a β -halogenethyl-*p*-aminobenzoic ester (see preceding abstract). Thus diethylamine and ethyl β -chloroethyl-*p*-aminobenzoate give ethyl β -diethylaminoethylaminobenzoate, an oily liquid which yields a monohydrochloride when evaporated to dryness with the requisite quantity of dilute hydrochloric acid. On recrystallising from alcohol white needles are obtained, melting at 156° C.—G. F. M.

Substituted benzoic acid esters; Manufacture of new —. Soc. Chim. des Usines du Rhône, Paris. Eng. Pat. 128,912, 7.6.19. (Appl. 14,550/19.) Int. Conv., 26.6.18.

DI- β -HALOGENETHYL-*p*-AMINOBENZOIC acid esters of the general formula, $(XCH_2CH_2)_2N.C_6H_4.CO_2R$ are obtained from the corresponding di- β -hydroxy compounds, by treating them with halogenating agents such as phosphorus or sulphur chlorides, thionyl chloride, etc., using tertiary amines etc. as diluents as described in Eng. Pat. 128,553 (preceding). Ethyl β -dichloroethyl-*p*-aminobenzoate prepared in this way melts at 53° C. and boils at 215° C. under 3 mm. pressure with slight decomposition. These dichloro-esters may be converted into dialkylamino esters of the general formula $(R.N.CH_2CH_2)_2N.C_6H_4.CO_2R'$, where R is a hydrogen atom or an alkyl group, and R' an alkyl group, by treating with an alkylamine as previously described (*loc. cit.*). The dialkylamino esters give

neutral dihydrochlorides which can be crystallised from alcohol.—G. F. M.

Acetone and carbonic acid; Manufacture of —. Soc. Anon. des Acieries et Forges de Firminy, Firminy, France. Eng. Pat. 131,143, 18.2.19. (Appl. 4019/19). Int. Conv., 16.11.18.

ACETIC acid of 90–100% strength is decomposed by the aid of a catalyst of manganese peroxide, either prepared by precipitation, or preferably natural pyrolusite, crushed and screened to pieces, of a diameter of 5–7 mm. Catalysis occurs without appreciable subsidiary reaction between wide limits of temperature, for instance from 350° to 450° C. The catalyst is packed in a cylinder and heated either externally, or preferably by mixing with 1–1½ volumes of crushed coke of similar dimensions and passing an electric current through the mixture by means of two iron or aluminium electrodes. Acetone is recovered from the product of catalysis by means of condensers and finally by scrubbing the uncondensed gas in water sprinkling towers, and the washed carbon dioxide is suitably stored for use. The spent catalyst can be revived by merely heating in a current of air.—G. F. M.

Dental cements. J. V. G. Andresen, Copenhagen. Eng. Pat. 134,757, 9.4.19. (Appl. 9048/19.)

A DENTAL cement is prepared by working up a mixture of 45 parts of zinc oxide and 15 parts of burnt alum into a paste with 22½ parts of water, or, to increase the local anæsthetic property of the cement, with 15 parts of oil of cloves, eugenol, or a concentrated solution of zinc sulphate, zinc chloride, copper sulphate, phosphoric acid, or mixtures of the same, or with the product obtained by heating 15 parts of eugenol with 2 parts of formaldehyde at 120° C.—L. A. C.

Maleic acid; Preparation of —. J. M. Weiss, New York, and C. R. Downs, Cliffside, N.J., Assignors to The Barrett Co. U.S. Pat. 1,318,632, 14.10.19. Appl., 27.5.18.

A MIXTURE of benzene and quinone in the vapour phase is oxidised by treatment under pressure with a gas containing oxygen at a temperature of 300°–700° C. in the presence of vanadium oxide as a catalyst. The maleic acid produced is separated and the residual benzene and quinone are again subjected to the same process.—G. F. M.

Acetylsalicylic acid; Purification of —. H. Hibbert, Mount Vernon, N.Y., Assignor to The Commercial Research Co. U.S. Pat. 1,321,307, 11.11.19. Appl., 8.4.16. Renewed 11.5.18.

CRUDE acetylsalicylic acid is dissolved in a hot dichlorinated hydrocarbon, e.g., ethylene dichloride, or the mixture obtained by chlorinating oil gas. Acetylsalicylic acid crystallises from the solution on cooling.—L. A. C.

Glycerin substitute. [Ester salts of phthalic acid.] O. Rössler, Dresden. Ger. Pat. 313,059, 23.8.17.

ESTER salts of phthalic acid soluble in water are used as glycerin substitutes. One carboxyl group of the phthalic acid is esterified with a monohydric alcohol and the other group is combined with a metallic base, such as sodium, to form a salt soluble in water. The ester salts are used in moderately dilute solution.—J. F. B.

Cholic acid; Manufacture of an acyl derivative of —. J. D. Riedel A.-G., Berlin-Britz. Ger. Pat. 313,413, 1.4.14.

ACETYLSALICYLIC acid chloride reacts with cholic acid in the presence of a compound capable of combining with hydrochloric acid, e.g., pyridine, to form a white crystalline powder, m.pt. 120° C., insoluble in water, and soluble in alcohol. The

product is tasteless and has no action on the digestion, but passes unchanged into the intestines, where it is dissolved and combines the cholagogic action of cholic acid with the antineuralgic properties of salicylic acid.—L. A. C.

Ethylidene esters; Production of —. Chem. Fabr. Griesheim-Elektron, Frankfurt. Ger. Pat. 313,696, 11.11.15.

ORGANIC vinyl esters are treated with organic or inorganic acids so as to couple one molecule of acid to the ester, e.g., equimolecular proportions of the components, with or without catalysts, are heated together under pressure until combination is complete; one vinyl ester or a mixture of several may be used. Vinyl acetate boiled with acetic acid and a little strong sulphuric acid gives ethylidene acetate. Vinyl benzoate and dry hydrogen chloride give chloroethyl benzoate. Vinyl acetate and benzoic acid give ethylidene acetobenzoate $\text{CH}_3\text{CH}(\text{CO}_2\text{CH}_3)(\text{CO}_2\text{C}_6\text{H}_5)$. Vinyl acetate and hydrogen chloride give chloroethyl acetate $\text{CH}_3\text{CO}_2\text{CHClCH}_2$. The products are generally excellent solvents for artificial and natural resins, nitro- and acetyl-celluloses, and can be used for the preparation of lacquers, films, impregnating preparations, etc.—H. J. H.

Organic substances ordinarily insoluble in water; Process of preparing aqueous solutions of —. E. Kolshorn, Munich. Ger. Pat. 313,726, 13.12.16.

AQUEOUS solutions of esters of carbanic acids are used to render certain organic compounds soluble in water without chemical change. Among the compounds which may be dissolved in this way by means of urethane are alcohols (amyl alcohol, benzyl alcohol, geraniol); bases (aniline, phenylhydrazine, quinoline, isoquinoline); alkaloids (quinine, morphine); drugs of various composition (paraldehyde, sulphonal, antipyrine, thymol, phenacetin, camphor); essential oils, and colouring matters. Ethylurethane, and higher and lower esters of carbanic acid, e.g., the methyl, propyl, isoamyl, allyl, and glyceryl esters, behave in the same way. The solutions prepared with such esters are stable and can be sterilised. By evaporating the solutions solid preparations are obtained consisting of a mixture of the solvent and dissolved substance, which on the addition of water are readily dissolved again.—C. A. M.

Organic compounds; Manufacture of heterocyclic —. M. Wiernik, Berlin-Schöneberg, G. and O. I. Grüttner, Charlottenburg. Ger. Pat. 313,876, 4.7.15.

A DIHALOGENPENTANE or a similar hydrocarbon derivative containing two reactive halogen atoms and an arsenic halide or an organo-arsenic halide are treated with sodium or magnesium in the presence of an indifferent solvent. A compound of any other metal or metalloid, with the exception of silicon and mercury, may be used in place of that of arsenic. The products are decomposed by halogens with the formation of the original dihalogenhydrocarbons. Examples: Cyclopentyl-ene-phenyl arsine, a colourless oil, sp. gr. 1.2420, b. pt. (20 mm.) 153°–154° C., is prepared by the action of sodium or magnesium on a mixture of 1.5-dibromopentane and phenyldichloroarsine. Cyclo-tetramethylenephénylphosphine, a colourless oil, sp. gr. 1.0502, b. pt. (16–18 mm.) 131°–134° C., is prepared from phosphorus phenylchloride and the magnesium derivative of 1,4-dibromobutane. A number of other examples are given.—L. A. C.

p-Phenetol-urea; Manufacture of —. J. D. Riedel A.-G., Berlin-Britz. Ger. Pat. 313,965, 22.3.17.

PHENETIDINE hydrochloride is added to an aqueous

solution of an alkali cyanide containing an alkaline oxidising agent such as sodium hypochlorite or sodium peroxide. *p*-Phenol-urea separates immediately in good yield and purity.—L. A. C.

Furfural; Manufacture of —. E. Ricard, Melle, France. U.S. Pat. 1,322,054, 18.11.19. Appl., 22.11.17.

See Eng. Pat. 129,025 of 1917; this J., 1919, 658 A. *Benzaldehyde*. U.S. Pat. 1,321,959. See III.

Anthranilic acid. U.S. Pat. 1,322,052. See III.

Urine. Eng. Pat. 131,710. See XXIII.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Sharp-cut selective [light] filters; Experiments in the use of — in spectro-photometric researches. I. *Dependence of gradation on wave-length with gelatino-bromide of silver*. A. Hnatek. Z. wiss. Phot., 1916, 15, 271—288.

SOME of the filters described in a previous paper (see preceding abstract) were used for determining the relation between the wave-length of the light, to which a plate is exposed, and the gradation of the resulting image. Exposures were impressed by means of a tubes-photometer (Eberhard's modification) with revolving plate-holder, which was first carefully calibrated by the aid of a series of uniformly exposed and developed plates of various densities which were found to be free from scattering effect and without selective spectral absorption. In order to obtain similar effective exposures with the same exposure-time for different colour-mixers and different plates, use was made of the same series of neutral densities to modify the intensity of the light in the gradation experiments. This use of an intensity scale permitted the employment of the expression $S = a + bm + cm^2$, in which S is the density of an image produced by a light-intensity I , $m = -2.5 \log. I$ and a , b , and c are constants which can be determined experimentally for each plate. Gradation, G , is then $dS/dm = b + 2cm$; in the case of certain plates, such as Seed plates with a very long straight-line portion of the sensitiveness-curve, $S = a + bm$ and $G = b$, i.e., is independent of the intensity of the light. The wave-lengths of the colour filters were taken as the "effective" wave-lengths, i.e., in each case the wave-length indicated by the mass-centre of the area included between the horizontal axis and the spectrum curve of the particular light-filter and plate; effective wave-lengths were determined for the Elko plate as representing ordinary plates, and for the colour plate as representing orthochromatic plates. A number of tables are given of the results with five brands of ordinary plates and three brands of colour-sensitive plates (not panchromatic). The filters were selected in each case to cover the range of spectral sensitiveness of the plate. The curves obtained by plotting gradation against wave-length show in all cases an S-formation, rising from short wave-lengths up to a maximum, for ordinary plates at about $\lambda = 4500\mu$, falling to a minimum, and then rising again to about 4900μ ; the chromatic plates show more variation both as to the position of the maximum and its height.—B. V. S.

PATENT.

Coloured [photographic] picture; Process and apparatus for production of a —. J. H. Christensen, Sölleröd, Denmark. Ger. Pat. 313,836, 24.7.18. Int. Conv., 13.8.17.

In a colour process in which three colour records

are taken on one double-coated film and one single-coated film, the two films after completion of the partial colour pictures being cemented together, e.g., with glycerin, to form the complete picture, one or both of the coated films is stretched in a special holder in which it remains until the various processes and the cementing are completed. Where two such frames are used registration is secured by an arrangement of pins and sockets, and one (or both) of the frames is provided with a spring edge under the film, in order to assist in obtaining perfect contact of the two films.—B. V. S.

Nitrocellulose. Oddo. See V.

XXIII.—ANALYSIS.

Temperature; Methods of determining —. Their application and reliability. K. Scheel. Z. angew. Chem., 1919, 32, 317—349.

A DESCRIPTION of various mercury, alcohol, toluene, and pentane thermometers, thermo-couples, resistance pyrometers, radiation pyrometers, and Seger cones. For standardising thermometers, especially mercury thermometers, the following fixed points are given:—*Melting points*: Mercury, -38.89° ; ice, 0° ; tin, 231.85° ; cadmium, 320.9° ; zinc, 419.4° ; antimony, 630° ; silver, 960.5° ; gold, 1063° ; copper, 1083° ; palladium, 1157° ; platinum, 1761° C. The transition point of crystallised sodium sulphate is 32.38° C. *Boiling points*: Oxygen, -183.0° C. + $0.01258(p-760) - 0.000007(p-760)^2$; carbon dioxide, -78.5° C. + $0.01595(p-760) - 0.000011(p-760)^2$; naphthalene, 217.96° C. + $0.058(p-760)$; benzophenone, 305.9° C. + $0.0663(p-760)$; sulphur, 444.55° C. + $0.0908(p-760) - 0.000047(p-760)^2$. p is the barometric pressure.—W. P. S.

Filtration; Method for rapid [laboratory] —. J. D. van Leeuwen. Chem. Weekblad, 1919, 16, 1424—1425.

THE author has obtained satisfactory results with the method proposed by Noyes (Int. Sugar J., May, 1919), in which, by tearing off a corner from one or two thicknesses of the folded filter paper, an unbroken stream of liquid is obtained in the stem of the funnel, filtration being thereby accelerated.

—W. J. W.

Charcoal sticks; Preparation of — for reduction tests. N. C. Alexandrescu. Bul. Soc. Chim. Romania, 1919, 1, 11—12.

SMALL wood sticks, as used for making matches, are boiled for two minutes with a 25% solution of ammonium phosphate and then dried at a temperature not exceeding 60°C ., and stored in a stoppered bottle. To carry out the ordinary qualitative charcoal test, half of a stick is burnt, and then the test is carried out in the usual manner on the substance previously mixed with sodium carbonate.

—W. G.

Gas analysis apparatus. M. Bürgerhausen. Chem.-Zeit., 1919, 43, 731.

In the compact apparatus described the absorption vessels are so constructed that the gas, on entering the vessel, bubbles through the solution; a three-way tap allows the return of the gas to the measuring burette. "Dead space" in the connecting capillary tubes is reduced to a minimum. The wires of the combustion pipette are fitted through a tubulure at the top of the pipette.—W. P. S.

Electrometric analysis with potassium ferrocyanide. E. Müller. Z. angew. Chem., 1919, 32, 351—352.

THE electrometric titration of metals with

potassium ferrocyanide solution fails in many cases owing to the fact that the precipitates produced are not of constant composition. The method, however, is trustworthy for the determination of lead or zinc; in the case of zinc, the method is more reliable than is the ordinary method of titration, using uranium nitrate as an external indicator, since small quantities of cadmium do not interfere.

—W. P. S.

Iron; Iodometric estimation of — I. M. Kolthoff. Pharm. Weekblad, 1919, 56, 1565—1568.

THE estimation of ferrous iron by means of iodine and a pyrophosphate gives low results owing to oxidation of the iodine by dissolved oxygen. Removal of the oxygen by means of sulphuric acid and sodium bicarbonate reduces the error. A more convenient method consists in adding potassium bromate and phosphoric acid to the acidified iron solution, allowing to stand, and then adding potassium iodide and a few drops of molybdate solution, the iodine being finally titrated back with thiosulphate. (See also this J., 1919, 444 A.)

Iron, aluminium, chromium, glucinum, titanium, and zirconium; Separation of — by means of sodium carbonate. P. Wenger and J. Wuhrmann. Ann. Chim. Analyt., 1919, 1, 337—339.

WUNDER and Wenger have shown (this J., 1912, 664) that fusion with sodium carbonate affords a means of separating iron and glucinum oxides from aluminium and chromium, the two latter forming compounds which are soluble in water, and the authors now extend the method to the analysis of similar mixtures also containing titanium or zirconium oxides. Titanium oxide, however, interferes with the separation of iron from zirconium, and the latter renders impossible the separation of iron and titanium oxides. In the absence of titanium, iron and zirconium oxides, obtained as an insoluble precipitate after fusion as described with sodium carbonate may be separated from each other by taking advantage of the insolubility of zirconium oxide in hydrochloric acid (1:1). If zirconium is absent, iron and titanium oxides, even in the presence of glucinum oxide, may be separated by one of the known methods.—W. P. S.

Zirconium; Estimation of — by the phosphate method. G. E. F. Lundell and H. B. Knowles. J. Amer. Chem. Soc., 1919, 41, 1801—1808.

Zirconium can be quantitatively precipitated as secondary zirconium phosphate in cold or tepid solutions containing 2—20% by weight of sulphuric acid, provided that a 10—100-fold excess of the precipitant, di-ammonium phosphate, is used. Hydrolysis, which occurs when the phosphate precipitate is washed with water, can be almost entirely avoided by the use of a cold 5% ammonium nitrate solution for washing. Zirconium pyrophosphate, for which the factor (ZrO_2) is 0.4632, is obtained on ignition of secondary zirconium phosphate which has been washed with ammonium nitrate solution. No definite composition can be assigned to the compound resulting when secondary zirconium phosphate, which has been washed with water, is ignited. Zirconium can be quantitatively separated as phosphate in a 20% sulphuric acid solution from iron, aluminium, chromium, cerium, and thorium. The separation from titanium can also be effected provided that hydrogen peroxide is present.
